A person who feels sexually aroused by fantasies, urges, and behaviors that inflict physical or psychological suffering on another person is said to have **sexual sadism** (see Table 11.3). Note that sexual sadism involves *real* acts that cause someone else to suffer (versus simulated acts, where no real suffering occurs). There are two sets of circumstances in which someone would be diagnosed with sexual sadism: (1) The recurrent sadistic fantasies or urges cause the individual significant distress, such as occurs when a man is horrified to discover that he is consistently aroused when fantasizing about hurting his partner; or (2) the individual has repeatedly subjected a nonconsenting partner to sexually sadistic acts (as occurs with sadistic rape)—such behavior is also a criminal act.

Pedophilia

A paraphilia characterized by recurrent sexually arousing fantasies, sexual urges, or behaviors involving a child who has not yet gone through puberty (typically aged 13 or younger).

Sexual sadism

A paraphilia characterized by recurrent sexually arousing fantasies, urges, and behaviors that inflict physical or psychological suffering on another person.

Any type of rape is a criminal act; sadistic rape—while criminal—is also a type of sexual sadism, as defined in DSM-IV-TR. What distinguishes sadistic rape from other forms of rape is that in the former the offender becomes sexually aroused by gratuitous violence or the victim's suffering or humiliation (Heil & Simons, 2008). In contrast, nonsadistic rape occurs when the rapist uses force in order to get his victim to “comply,” but not because such force is a critical element of his sexual arousal pattern (Yates, Hucker, & Kingston, 2008).

For those diagnosed with sexual sadism, the sadistic sexual fantasies were often present in childhood, and the sadistic behavior commonly began in early adulthood—as occurred with the man in Case 11.4. Sexual sadism is usually chronic, and the severity of the sadistic behaviors increases over time (American Psychiatric Association, 2000).

CASE 11.4 ► FROM THE OUTSIDE: Sexual Sadism

A physician, raised alone by his widowed mother since age 2, has been preoccupied with spanking's erotic charge for him since age 6. Socially awkward during adolescence and his 20s, he married the first woman he dated and gradually introduced her to his secret arousal pattern of imagining himself spanking women. Although horrified, she episodically agreed to indulge him on an infrequent schedule to supplement their frequent ordinary sexual behavior. He ejaculated only when imagining spanking. Following her sixth episode of anxious, sullen depression in 20 years of marriage, her psychologist instructed her to tell him “No more.” He fell into despair, was diagnosed with a major depressive disorder, and wrote a long letter to her about why he was entitled to spank her. He claimed to have had little idea that her participation in this humiliation was negatively affecting her mental health (“She even had orgasms sometimes after I spanked her!”). He became suicidal as a solution to the dilemma of choosing between his or her happiness and becoming conscious that what he was asking was abusive. He was shocked to discover that she had long considered suicide as a solution to her marital trap of loving an otherwise good husband and father who had an unexplained sick sexual need.

(Sadock & Sadock, 2007, pp. 709–710)

Sexual Masochism: Receiving the Pain

Whereas sexual sadism involves hurting others, **sexual masochism** is characterized by recurrent sexual arousal in response to fantasies, urges, or behaviors related to being hurt—specifically, being humiliated or made to suffer in other ways (see Table 11.3; American Psychiatric Association, 2000). Moreover, for a diagnosis of sexual masochism, the sexual fantasies, urges, and behavior must cause significant distress or impair functioning.

Sexual masochism is diagnosed in both men and women and is, in fact, the only paraphilia that occurs at measurable rates among women (Levitt, Moser, & Jamison, 1994). One study found that about a quarter of women who engage in sexually masochistic behavior reported a history of sexual abuse during childhood, which suggests that the abuse made them more likely to be aroused by masochistic acts (Nordling, Sandnabba, & Santtila, 2000). However, these women did not necessarily have sexual masochism, because they did not report distress or impaired functioning because of their sexual preferences.

Some people with sexual masochism inflict the pain or humiliation on themselves, whereas others rely on someone else to do this to them. Some people with sexual masochism may also have sexual sadism, alternating the role they assume. They may also have fetishism or transvestic fetishism, which we discuss next.

Paraphilias Involving Nonhuman Objects

Two paraphilic disorders—fetishism and transvestic fetishism—are characterized by persistent sexual fantasies, urges, and behaviors that focus on nonhuman animals or objects, such as clothing, which lead to significant distress or impair functioning.

Sexual masochism

A paraphilia in which the individual repeatedly becomes sexually aroused by fantasies, urges, or behaviors related to being hurt—specifically, being humiliated or made to suffer in other ways—and this arousal pattern causes significant distress or impairs functioning.

Newscom

The hallmark of the paraphilia fetishism is being sexually aroused by inanimate objects, such as footwear or mannequins.

Fetishism

A paraphilia in which the individual repeatedly uses nonliving objects to achieve or maintain sexual arousal and such an arousal pattern causes significant distress or impairs functioning.

Transvestic fetishism

A paraphilia in which a heterosexual man cross-dresses in women's clothes for sexual arousal and experiences distress or impaired functioning because of the cross-dressing; formerly called *transvestism*.

Fetishism: Sexually Arousing Objects

Fetishism is the paraphilia characterized by the repeated use of nonliving objects, such as women's shoes or undergarments, in sexual fantasies, urges, or behaviors, which in turn leads to distress or impaired functioning (see Table 11.3). The object—termed a *fetish*—may be used to achieve sexual arousal or to maintain an erection with a partner or alone. For instance, a man with a shoe fetish will become aroused by seeing or smelling women's footwear. He may steal women's shoes and use them to masturbate (Shiah et al., 2006). When fetishism is severe, he may be unable to have sexual relations with a partner unless the fetish is part of the sexual experience. When the fetish is a nonsexual body part, such as a foot, the paraphilia may be referred to as *partialism*. The DSM-IV-TR definition of fetishism, however, does not include partialism (and so a foot fetish is technically classified as a paraphilia not otherwise specified).

A survey of hospital discharge summaries of men with fetishism (Chalkley & Powell, 1983) found that:

- 60% preferred items of clothing (as did the man in Case 11.5);
- 25% were aroused by items of rubber;
- 15% were aroused by footwear;
- 15% had partialism; and
- 37% regularly stole items of their preferred fetish.

People with fetishism generally come to the attention of mental health professionals only after being apprehended for the theft of their fetish.

CASE 11.5 ► FROM THE OUTSIDE: Fetishism

A single, 32-year-old male free-lance photographer presented with the chief complaint of “abnormal sex drive.” The patient related that although he was somewhat sexually attracted by women, he was far more attracted by “their panties” . . . His first ejaculation occurred at 12 via masturbation to fantasies of women wearing panties. He masturbated into his older sister's panties, which he had stolen without her knowledge. Subsequently he stole panties from her friends and other women he met socially. He found pretexts to “wander” into bedrooms of women during social occasions, and would quickly rummage through their possessions until he found a pair of panties to his satisfaction. He later used these to masturbate into and then “saved them” in a “private cache.” The pattern of masturbating into women's underwear had been his preferred method of achieving sexual excitement and orgasm from adolescence until the present consultation . . . he felt anxious and depressed because his social life was limited by his sexual preference.

(Spitzer et al., 2002, p. 247)

Transvestic Fetishism: Cross-Dressing for Sexual Arousal

Formerly called *transvestism*, **transvestic fetishism** is the diagnosis given to heterosexual men who cross-dress in women's clothes for sexual arousal and experience distress or impaired functioning because of it (Table 11.3), as Mike did. (Note that this is in contrast to men with gender identity disorder, who dress as women *not* for sexual arousal but to make their outward appearance more congruent with their internal experience; see Table 11.4.) Moreover, men with transvestic fetishism use female clothing differently than those with a nontransvestic fetish that involves female apparel, such as an underwear fetish. Men with a nontransvestic fetish may wear female clothes to achieve sexual arousal, but only if the clothes were previously worn by a woman; they do not try to appear female, as Jenny Boylan, in Case 11.1, did. In contrast, men with transvestic fetishism wear *new* female clothes and try to appear as female, as Mike did.

Transvestic fetishism usually begins in childhood; most men with this disorder began cross-dressing before age 10. As adults, the cross-dressing usually is not limited to the privacy of the home: Almost three quarters of men with this disorder who

Table 11.4 ▶ Transvestic Fetishism Versus Gender Identity Disorder

Transvestic Fetishism	Gender Identity Disorder
Gender identity same as biological sex	Gender identity opposite of biological sex
Comfortable with own biological sex	Want to be the other sex
Cross-dress for sexual arousal or to feel “calmer”	Cross-dress for congruence between appearance and gender identity

were surveyed reported that they had appeared in public while dressed as women. Almost two thirds are married, often with children; you may assume that they hide their fetish from their wives, but as with Mr. A., in Case 11.6, the wives often know about the cross-dressing. Most wives are ambivalent about it, and less than a third accept it (Docter & Prince, 1997).

CASE 11.6 ▶ FROM THE OUTSIDE: Transvestic Fetishism

Mr. A., [is] a 65-year-old security guard [married and with grown children], formerly a fishing-boat captain. . . . His first recollection of an interest in female clothing was putting on his sister's [underwear] at age 12, an act accompanied by sexual excitement. He continued periodically to put on women's underpants—an activity that invariably resulted in an erection, sometimes a spontaneous emission, and sometimes masturbation, but was never accompanied by fantasy. Although he occasionally wished to be a girl, he never fantasized himself as one. He was competitive and aggressive with other boys and always acted “masculine.” During his single years he was always attracted to girls, but was shy about sex. Following his marriage at age 22, he had his first heterosexual intercourse.

His involvement with female clothes was of the same intensity even after his marriage. Beginning at age 45, after a chance exposure to a magazine called *Transvestia*, he began to increase his cross-dressing activity. He learned there were other men like himself, and he became more and more preoccupied with female clothing in fantasy and progressed to periodically dressing completely as a woman. . . . Over time [his cross-dressing] has become less eroticized and more an end in itself, but it still is a source of some sexual excitement. He always has an increased urge to dress as a woman when under stress; it has a tranquilizing effect. If particular circumstances prevent him from cross-dressing, he feels extremely frustrated.

(Spitzer et al., 2002, pp. 257–258)

Assessing Paraphilic Disorders

The paraphilias are usually assessed by examining neurological (sometimes reflected by bodily responses), psychological, or social factors. Sexual arousal in men can be measured by a *penile plethysmograph*, which is an indirect measure of neurological events. The device is placed on a man's penis and measures penile rigidity. The man is then shown “normal” and “deviant” stimuli (such as photos of footwear or whips), and the rigidity of the penis is measured after each stimulus is presented. If the plethysmograph registers unusual amounts of arousal when the man views deviant stimuli, compared to stimuli that induce arousal in men without a paraphilia, this response suggests that he has a paraphilia.

In addition, researchers have recorded brain electrical activity while “normal” heterosexual men and men with paraphilias viewed “normal” erotic, “deviant” erotic (such as typical fetish objects), or neutral stimuli (such as a street scene). Men with paraphilias showed greater activation in the left frontal lobe (which typically reflects the presence of an “approach emotion,” Davidson, 2002) when viewing deviant erotic stimuli than men without paraphilias, but men without paraphilias showed greater activation in the right parietal lobe when viewing normal erotic stimuli (which may reflect increased attention or other visual processing; Waismann et al., 2003).

Self-reports of arousal (psychological factor) are also used to assess paraphilic disorders: Men describe what they find sexually arousing, either to a mental health clinician or in response to a questionnaire. Finally, assessment of paraphilias may rely on reports from partners or the criminal justice system (social factor), when men are apprehended for engaging in illegal sexual activity such as exhibitionism or pedophilia (McAnulty, Adams, & Dillon, 2001).

Criticisms of the DSM-IV-TR Paraphilias

Critics of the set of paraphilic disorders identified in DSM-IV-TR point out that such disorders are, in essence, behaviors and fantasies that Western culture currently labels as “deviant”; such deviance is relative to the current cultural concept of “normal” sexual behavior or fantasies (Moser & Kleinplatz, 2005). Normal sexual behavior typically has been defined by the church, the government, or the medical community. Moreover, labeling certain sexual behaviors or urges as deviant has been done throughout history, although the specific behaviors or urges have varied across cultures and over time. For instance, homosexuality, masturbation, and oral sex have at various points in time in various cultures been considered unacceptable deviations from normal sexuality. Sexual deviations have been considered sinful, criminal, or sick, and the responses to such deviations have included penitence, punishment, or “cure” (McAnulty, Adams, & Dillon, 2001; Moser, 2001).

However, we must stress that, according to DSM-IV-TR, the issue isn’t simply having unusual sexual interests, but rather that these interests or their related behaviors cause significant distress or significantly impair functioning (Moser, 2009).

Another criticism is that some sex crimes are included as just another type of paraphilia. Such crimes that may meet the criteria for a paraphilia include exhibitionism, voyeurism, frotteurism, pedophilia, and sexual sadism. As one researcher in the field points out:

Some sex crimes are not diagnoses (e.g., rape) and some Paraphilia diagnoses are not crimes (e.g., Fetishism, Sexual Masochism, consensual Sexual Sadism, and Transvestic Fetishism). Some sexual interests were both crimes and diagnoses, but are no longer (e.g., homosexuality). . . . Some sexual behaviors were psychiatric disorders and were believed to cause a variety of physical disorders, but are now considered healthy (e.g., masturbation). . . . What is defined as “normal” sexual behavior, what is a mental disorder, what is a crime, and what constitutes a sex crime do change over time.

(Moser, 2009, p. 324)

Including such a large range of diverse disorders limits the kinds of generalizations that can be made about the paraphilias. Specifically, the diagnosis of some of the paraphilias depends on the fact that the object of desire does not consent to the sexual interaction, whereas others paraphilias do not involve coercion—and may not involve another person at all.

And even among patients with paraphilias that are directed toward nonconsenting victims, we can further distinguish distinct groups of patients. For instance, some patients prefer normal sexual activity but have deviant fantasies of coercing others, which cause them distress; in contrast, other patients meet the criteria solely because of their behavior (that is, they may molest children or sadistically rape someone), but they may not feel any distress about this behavior. Both types of individuals would be diagnosed with a paraphilic disorder directed toward nonconsenting partners (McAnulty, Adams, & Dillon, 2001).

Similarly, DSM-IV-TR does not take into consideration how well an individual can overcome his urges and *not* engage in a paraphilic behavior. The capacity to restrain the behavior should be particularly important with paraphilias that involve nonconsenting partners. A man may have fantasies of exposing himself or fondling a child, but if he is always able to restrain himself from acting out those fantasies, he is not a danger to anyone; nevertheless, if his fantasies and urges cause him distress or impair his ability to function, he would be diagnosed with pedophilia.

Finally, as we discuss in the following section, some researchers have suggested that paraphilias should be considered a type of obsessive-compulsive disorder (OCD).

Understanding Paraphilias

Researchers are only just beginning to learn why paraphilias emerge and persist, and not enough is known to understand how feedback loops might arise among neurological, psychological, and social factors. However, some facts related to these factors—and their interactions—have been reported, including neurological similarities to OCD and the role of classical conditioning in sexual arousal.

Neurological Factors

Many theorists who have considered the neurological underpinnings of paraphilias have noted the apparent similarities between these disorders and OCD, both of which involve obsessions and compulsions. As discussed in Chapter 7, OCD appears to arise from abnormal functioning in a neural system that includes the basal ganglia (which play a central role in producing automatic, repetitive behaviors) and the frontal lobes (which normally inhibit such behaviors). In fact, researchers found that people with pedophilia have very specific cognitive deficits when performing tasks that rely on this neural system (Tost et al., 2004). For example, these patients were strikingly impaired in inhibiting responses and in working memory—both of which rely heavily on the frontal lobes (Smith & Kosslyn, 2006).

In addition, evidence suggests that the neurotransmitters that are used in this neural system, such as dopamine and serotonin, do not function properly in people who have paraphilias (Kafka, 2003). Indeed, SSRIs decrease the sexual fantasies and behaviors related to paraphilias, which is consistent with the view that neural interactions involved in OCD are also involved in the paraphilias (Abouesh & Clayton, 1999; Bradford, 2001; Kafka & Hennen, 2000; Roesler & Witzum, 2000).

Finally, there is a hint that genes contribute to the paraphilic disorders. For example, researchers have identified monozygotic twins who have both paraphilias and OCD (Cryan, Butcher & Webb, 1992). In addition, researchers have found that paraphilias have a slight tendency to run in families; moreover, pedophilia occurs more frequently in families in which a member has pedophilia than in families in which members have another sort of paraphilia (Gaffney, Lurie, & Berlin, 1984). If such findings are replicated, they would suggest that distinct sets of genes contribute to pedophilia.

Psychological Factors: Conditioned Arousal

Both psychodynamic and cognitive-behavioral theories have been invoked to explain paraphilias, but research to date does not generally support either type of explanation (Osborne & Wise, 2005). Behavioral theory, though, can answer one intriguing question about paraphilias: Why are almost all people with paraphilias male? One contributing factor may simply stem from male physiology: The position of the penis and testicles on the body can easily lead to their being inadvertently stimulated (Munroe & Gauvain, 2001); this is important because such stimulation can result in classical conditioning.

Classical conditioning principles can explain how certain objects or situations come to produce sexual arousal in general, and paraphilias in males in particular (Domjan, Cusato, & Krause, 2004; Köksal et al., 2004). Consider this example: A fetish for objects such as women's shoes can develop when an unconditioned stimulus that led to sexual arousal became paired with a conditioned stimulus (women's shoes). Thus, a boy who coincidentally saw his mother's shoes before—intentionally or accidentally—touching his penis may come to have a conditioned response of sexual arousal to women's shoes in the future. Moreover, the pleasurable consequence of arousal and possible orgasm provides positive reinforcement (Laws & Marshall, 1991). And, as discussed in Chapter 2, classical conditioning alters neural communication so that neurons that store particular associations come to fire together more easily. In fact, humans—or at least human males—may be biologically prepared to develop classically conditioned sexual arousal to some situations or objects (Osborne & Wise, 2005), which would explain why a pillow fetish is not a common fetish.

Some men who fought in World War II developed what would be considered a paraphilia: These men, who were in their formative years during the war, spent time with women who wore gas masks and bathrobes, and such attire became a sexual turn-on for the men (Kaplan, 1991).

Classical conditioning may be amplified by the *Zeigarnik effect* (Deutsch, 1968), which makes people more likely both to recall interrupted activities than ones that they finished and to try to complete interrupted activities when later allowed to do so. Applied to paraphilias, sexual arousal that has been associated with an object or situation may be such an interrupted activity: Sexual arousal at a young age that isn't allowed expression at that time becomes "interrupted"; the person is later driven to "complete" the interrupted activity. A sexual Zeigarnik effect is more likely to occur in males because of the nature of male anatomy, thus accounting for the predominance of men among those with paraphilias (Munroe & Gauvain, 2001).

Social Factors: More Erotica?

The Zeigarnik effect can also help explain why traditional, nonindustrialized societies have lower prevalence of paraphilias than do Western societies: Western societies provide many erotic stimuli—in magazines, in movies, and on billboards and television—to which males can become aroused. In turn, males, particularly boys, are thus more likely to be "interrupted," leading to a desire to complete the task (Munroe & Gauvain, 2001).

To summarize, three main factors appear to contribute to paraphilias: a neurological similarity to OCD, classical conditioning of sexual arousal, and the Zeigarnik effect. One hypothesis for the almost exclusive prevalence of these disorders among males pertains to how the male anatomy promotes more frequent and easier accidental sexual arousal, along with the consequences of being interrupted while aroused (the Zeigarnik effect).

Treating Paraphilias

Only some people who have paraphilias receive treatment—typically those who engaged in predatory paraphilic behavior with nonconsenting individuals and so were brought into the criminal justice system (where they are classified as *sex offenders*). The goal of treatment, which may be ordered by a judge, is to decrease paraphilic impulses and behaviors by targeting neurological, psychological, and social factors; research on treatments for paraphilic disorders is not yet advanced enough to indicate how feedback loops arise as a result of treatment.

Targeting Neurological and Other Biological Factors: Medication

One goal of treatment for men who have engaged in predatory paraphilic behaviors with nonconsenting individuals is to decrease or eliminate their sex drive. *Chemical castration* refers to the use of medications to achieve this goal. Medications include antiandrogen drugs such as *medroxyprogesterone acetate* (Depo-Provera) and *cypotereone acetate* (Androcur), which decrease testosterone levels. In turn, decreased testosterone levels lead to decreased sexual urges, fantasies, and behaviors in sexual offenders (Bradford, 2000; Gijs & Gooren, 1996; Robinson & Valcour, 1995). However, these medications don't necessarily diminish men's paraphilic *interests* along with sex drive. Moreover, within a few weeks of stopping the medication, the men again experience the urges and may engage in the predatory behaviors (Bradford, 2000; Gijs & Gooren, 1996).

In addition, as noted earlier, SSRIs may help decrease the sexual fantasies, urges, and behaviors in men whose paraphilic disorder has obsessive-compulsive elements (Abouesh & Clayton, 1999; Bradford, 2001; Kafka & Hennen, 2000; Roesler & Witzum, 2000). Thus, a treatment that targets neurological factors can affect thoughts (fantasies), which are psychological factors.

Targeting Psychological Factors: Cognitive-Behavior Therapy

CBT may be used to decrease cognitive distortions that promote paraphilic fantasies, urges, and behaviors. For example, such distortions might include the belief that sexual actions directed toward nonconsenting individuals are not harmful. Behavioral

AFP Photos/Newscom

Most men who receive treatment for a paraphilia do so after coming to the attention of the criminal justice system, as did this man.

methods, such as extinction, are designed to decrease sexual arousal to paraphilic stimuli while increasing arousal to normal stimuli (Akins, 2004). Treatment for sex offenders may involve both medication and CBT (Heilbrun et al., 1998). Both types of interventions, when effective, ultimately change arousal patterns, sexual fantasies and urges, and sexual behaviors toward nonconsenting individuals.

In addition, treatment may sometimes include *relapse prevention training*, which teaches men to identify and recognize high-risk situations and learn strategies to avoid them. Such training also involves learning new coping skills, such as anger management or assertiveness (Pithers, 1990). However, such treatments tend not to reduce subsequent offenses among those sex offenders who are also *psychopaths*—people who lack empathy, show little remorse or guilt about hurting others, and shirk responsibility for their actions (Barbaree, 2005; Langton et al., 2006).

Targeting Social Factors

Some treatments for sex offenders target social factors, for example, by training these men to empathize with victims in the hopes that they will be less likely to reoffend in the future (Marshall, O'Sullivan, & Fernandez, 1996). However, many offenders do not complete psychosocial treatments (Hanson, Bloom, & Stevenson, 2004; Langevin, 2006). Furthermore, such treatments have not been found to be very successful (Hanson, Bloom, & Stephenson, 2004).

In sum, most men who receive treatment—of any type—for a paraphilic disorder do so because their paraphilic behavior involves nonconsenting people; treatment typically is instigated by the criminal justice system. In this context, the goal of treatment is to reduce the likelihood of reoffending—of *acting* on the paraphilic urges. Treatments that target neurological factors primarily influence the behaviors, but not the underlying fantasies or urges; CBT addresses both the behaviors and the fantasies.

Key Concepts and Facts About Paraphilias

- Paraphilias are characterized by a predictable sexual arousal pattern regarding “deviant” fantasies, objects, or behaviors. Paraphilias can involve (1) nonconsenting partners or children (exhibitionism, voyeurism, frotteurism, and pedophilia), (2) suffering or humiliating oneself or one’s partner (sexual masochism and sexual sadism), or (3) arousal by nonhuman objects (fetishism and transvestic fetishism). To be diagnosed with a paraphilia, either the person must have acted on these sexual urges and fantasies, or these arousal patterns must cause the patient significant distress.
- Assessments of paraphilias may involve the use of a penile plethysmograph to determine the sorts of stimuli that arouse a man, as well as self-reports of arousing stimuli and reports from partners and from the criminal justice system for those apprehended for sexual crimes.
- Criticisms of the DSM-IV-TR paraphilia classification include the following: What is determined to be sexually “deviant” varies across cultures and over time; the diagnostic criteria are overly broad (e.g., fantasies or behavior, distress or no distress) and thereby lead clinicians to group together very different disorders (that is, to create a heterogeneous group); and the criteria do not address the ability to control the paraphilic urges.
- Research shows that paraphilias share similarities with OCD. Additional possible contributing factors include classically conditioned arousal and the Zeigarnik effect.
- Most frequently, men who receive treatment for paraphilias were ordered to do so by the criminal justice system. Treatments that target neurological factors decrease paraphilic behaviors through medication; however, although the behaviors may decrease, the interests often do not. Treatments that target psychological factors are designed to change cognitive distortions about the predatory sexual behaviors, especially the false belief that the behavior is not harmful to the nonconsenting victims. A goal of such treatments is to change sexual arousal patterns using behavioral methods, as well as to prevent relapse. Although social factors may be the target of treatment for sex offenders, they have not generally been successful.

Making a Diagnosis

- Reread Case 11.2 about Tom, and determine whether or not his symptoms meet the diagnostic criteria for exhibitionism. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

- Reread Case 11.3 about Charles, and determine whether or not his symptoms meet the criteria for frotteurism. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.4 about the physician who spanked his wife, and determine whether or not his symptoms meet the criteria for sexual sadism. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Do you think the physician's wife should be diagnosed with sexual masochism? List the criteria that apply to her, and which do not. If you would like more information to determine whether she should be diagnosed with sexual masochism, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.5 about the 32-year-old man, and determine whether or not his symptoms meet the criteria for fetishism. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.6 about Mr. A, and determine whether or not his symptoms meet the criteria for transvestic fetishism. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Sexual Dysfunctions

Let's return to Laura and Mike, the married couple whose relationship—and sex life—had become strained. Laura found that she didn't particularly miss having sexual relations with Mike. She did wonder how they had gotten to this point. In fact, Laura didn't have any sex drive, and the few times she and Mike had made love, nothing “happened” for her—she didn't have an orgasm or even find herself aroused. She couldn't pinpoint where things had gone astray; she'd like to feel desire, to *want* to have sexual relations with her husband, but she just didn't know where to start or how to get herself worked up about it. Was there something wrong with their relationship, or with her? Or is such lack of interest entirely “normal”?

An Overview of Sexual Functioning and Sexual Dysfunctions

People engage in sexual relations for two general reasons: to create babies (reproductive sex) and for pleasure (recreational sex). The vast majority of sexual acts are for pleasure, as opposed to procreation. Researchers have defined the “normal” progression of sexual pleasure as the *human sexual response cycle*, discussed below. **Sexual dysfunctions** are characterized by problems in the sexual response cycle. Let's first examine this cycle and then consider various ways in which it can go awry for men and women.

The Normal Sexual Response Cycle

What is a normal sexual response? In the 1950s and 1960s, researchers William Masters and Virginia Johnson sought to answer this question by measuring in their laboratory the sexual responses of thousands of volunteers. Based on their research, Masters and Johnson outlined the **sexual response cycle** for both women and men as consisting of four stages (see Figure 11.2): excitement, plateau, orgasm, and resolution (Masters & Johnson, 1966). Although it is convenient to organize these events into stages, the boundaries between these stages are not clear-cut (Levin, 1994):

1. **Excitement.** Excitement occurs in response to sensory-motor, cognitive, and emotional stimulation that leads to erotic sensations or feelings. Such arousal includes muscle tension throughout the body and engorged blood vessels, especially in the genital area. In men, this means that the penis swells; in women, this means that the clitoris and external genital area swell and vaginal lubrication occurs.
2. **Plateau.** Bodily changes that began in the excitement phase become more intense and then level off when the person reaches the highest level of arousal.

Sexual dysfunctions

Sexual disorders that are characterized by problems in the sexual response cycle.

Sexual response cycle

The four stages of sexual response—excitement, plateau, orgasm, and resolution—outlined by Masters and Johnson.

3. **Orgasm.** The arousal triggers involuntary contractions of internal genital organs, followed by ejaculation in men. In women, responses range from extended or multiple orgasms (without falling below the plateau level) to resolution.
4. **Resolution.** Following orgasm is a period of relaxation, of release from tension. For men, this period is often referred to as a *refractory period*, during which it is impossible to have an additional orgasm. Women rarely have such limitations and can often return to the excitement phase with effective sexual stimulation.

Other researchers have developed Masters and Johnson's ideas further. In particular, researchers now recognize that before the excitement phase, the person must first experience sexual attraction, which should lead to sexual desire, which in turn leads to the first stage of the sexual response cycle: excitement (Kaplan, 1981). According to DSM-IV-TR, *desire* consists of fantasies and thoughts about sexual activity along with an inclination or interest in being sexual (American Psychiatric Association, 2000). Sexual problems can occur when individuals experience a diminished—or even a lack of—sexual desire, or when they have difficulties related to sexual arousal or performance (the last three stages of sexual response). Laura appears to lack any sexual desire.

Figure 11.2

11.2 ▶ The Human Sexual Response Cycle

According to Masters and Johnson (1966), during the normal sexual response cycle, women and men go through four stages: excitement, plateau, orgasm, and resolution. However, women can experience multiple orgasms without a refractory period (a), whereas men must experience a refractory period before a subsequent orgasm (b).

Sexual Dysfunctions According to DSM-IV-TR

The DSM-IV-TR categories of disorders of sexual dysfunction were partly inspired by Masters and Johnson's sexual response cycle. Disorders of sexual dysfunction are divided into four categories: *sexual desire disorders*, *sexual arousal disorders*, *orgasmic disorders*, and *sexual pain disorders*. These disorders can arise in individuals of various sexual orientations: heterosexuals, lesbians, gay men, or bisexuals.

Someone can have more than one kind of sexual dysfunction, as when a man with premature ejaculation becomes nervous about having sexual relations and so develops a dysfunction of desire or arousal. Moreover, sexual dysfunction may have existed for an individual's entire adult life or been acquired after a period of normal sexual functioning, as happened to Laura. In addition, the dysfunction may occur in all circumstances (*generalized*) or only in certain situations, with specific partners or types of stimulation (*situational*). DSM-IV-TR also allows clinicians and researchers to note whether the sexual dysfunction is thought to be due to psychological rather than medical factors or due to a combination of psychological and medical factors. Table 11.5 lists the sexual dysfunctions and their diagnostic criteria.

As noted in Table 11.5, for a sexual dysfunction to be considered a disorder, the specific sexual symptoms must cause significant distress or relationship problems

Table 11.5 ► DSM-IV-TR Diagnostic Criteria for Sexual Dysfunctions

Type of Sexual Dysfunction	Female	Male
General Criteria	<p>A. The sexual dysfunction causes significant distress or interpersonal difficulties.</p> <p>B. The sexual dysfunction is not better accounted for by another Axis I disorder (except another Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (such as a drug of abuse, a medication) or a general medical condition.</p>	
Desire	<p><i>Hypoactive sexual desire disorder</i>: A. Persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and the context of the person's life.</p> <p><i>Sexual aversion disorder</i>: A. Persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner.</p>	
Arousal	<i>Female sexual arousal disorder</i> : A. Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, adequate lubrication or swelling during sexual excitement.	<i>Male erectile disorder</i> : A. Persistent or recurrent difficulty attaining or maintaining an adequate erection until sexual activity is completed.
Orgasm	<i>Female orgasmic disorder</i> : A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of Female Orgasmic Disorder should be based on the clinician's judgment that the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives.	<p><i>Male orgasmic disorder</i>: A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase during sexual activity that the clinician (taking into account the person's age) judges to be adequate in focus, intensity, and duration.</p> <p><i>Premature ejaculation</i>: A. Persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity.</p>
Pain	<p><i>Dyspareunia</i>: A. Recurrent or persistent genital pain associated with sexual intercourse in either a male or a female.</p> <p>B. The disturbance is not caused exclusively by a lack of lubrication.</p>	
	<i>Vaginismus</i> : A. Recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse.	

Note: To be diagnosed with a sexual dysfunction, the person must meet both the criteria for the specific sexual dysfunction and the general criteria.

(American Psychiatric Association, 2000). This means that someone may have a problem with any aspect of sexual response but would not be diagnosed as having a sexual dysfunction disorder unless the problem caused the individual marked distress or led to problems in his or her relationships.

Many, if not most, problems in the sexual response cycle have psychological causes rather than physical causes relating to the sex organs. This is true of both Mike and Laura, and somewhat true for Sarah and Benjamin, in Case 11.7. Table 11.6 provides more information about sexual dysfunctions.

CASE 11.7 ► FROM THE OUTSIDE: Sexual Dysfunctions

More than a decade [earlier], Sarah had experienced a very traumatic childbirth, with lacerations and ripping in the vaginal canal, which created extensive scarring and a lack of sensation. Since then she had found it difficult to become aroused and reach orgasm with intercourse. Before the delivery she had been fine.

Sarah had lost all interest in sex, but she was willing to be sexual for the sake of intimacy, which she still enjoyed. Her husband, Benjamin, however, had a hard time not taking it personally that she couldn't have an orgasm, and began to fixate on the problem, bringing it up in and out of the bedroom. But all the time and effort he was spending on her arousal only made her more anxious and less likely to become aroused at all. He started to feel inadequate as a result and began to find it difficult to maintain his erection. They had gone on in this way for years, and now were close to a separation.

(Berman et al., 2001, p. 168)

To understand better the problems Sarah and Benjamin were having, let's examine sexual dysfunctions in more detail.

Sexual Desire Disorders

Sexual desire is a multifaceted experience. It can be thought of as having at least three components: (1) a neurological and other biological component (related to hormones and brain activity, which lead to a genital response); (2) a cognitive component (related to an inclination or desire to be sexual); and (3) an emotional and relational component (related to being willing to engage in sex with a particular person at a specific place and time) (Levine, 1988). Any of these components can lead to either of two disorders, hypoactive sexual desire disorder or sexual aversion disorder.

Hypoactive Sexual Desire Disorder

As specified in DSM-IV-TR, one type of desire problem is **hypoactive sexual desire disorder**, whose hallmark is a persistent or recurrent lack of sexual fantasies or an absence of desire for sexual activity (see Table 11.5). This lack of desire may be lifelong or more recently acquired, and it may occur in all situations (generalized) or only in particular situations (such as with a specific person), but it must cause distress or impair functioning. Laura seems to have such a lack of sexual desire—a lack of any interest in sexual relations with Mike—but she wishes to feel desire.

Hypoactive sexual desire focuses primarily on a person's cognitive (fantasies) and emotional/relational (desire) state (Malatesta & Adams, 2001). People with hypoactive sexual desire disorder may lack sexual desire and be unwilling to engage in sexual behavior with a partner, or they may lack desire but still be willing to engage in sexual behavior with a partner, as was Sarah in Case 11.7. However, someone who is depressed and, as part of the depression, has little or no sexual desire (a symptom of depression) is not considered to have hypoactive sexual desire disorder because the low desire is caused by another disorder.

Women are more likely than men to have hypoactive sexual desire disorder. This sex difference may arise in part because, for women, desire may be more closely tied to the emotional nuances of a relationship than for men—as illustrated

Hypoactive sexual desire disorder

A sexual dysfunction characterized by a persistent or recurrent lack of sexual fantasies or an absence of desire for sexual activity.

Table 11.6 ▶ Sexual Dysfunctions Facts at a Glance**Prevalence**

- According to one survey of 1065 female and 447 male patients in a general medical practice, 22% of the men and 40% of the women had a “sexual dysfunction” in the preceding 4 weeks (Nazareth, Boynton, & King, 2003). However, the true prevalence of sexual dysfunctions is difficult to determine: Many surveys either equate sexual dissatisfaction—for any reason—with sexual dysfunction or use criteria that are different from those in DSM-IV-TR.
- In another survey, 35% of men and 54% of women who had at least one heterosexual partner in the previous year reported at least one sexual problem lasting 1 month (Mercer et al., 2003). Note, however, that this is not long enough for a diagnosis of sexual dysfunction.
- Only a small minority of respondents (6% of men, 16% of women) had persistent sexual problems that lasted more than 6 months (Mercer et al., 2003).
- According to one survey, although 40% of women reported sexual problems, only 12% reported *distress* about their problems (Shifren et al., 2008). Without distress (or impaired functioning), the diagnosis of a sexual dysfunction would not be made.

Comorbidity

- People with sexual dysfunctions may also have a co-occurring mood or anxiety disorder.

Onset

- A sexual dysfunction may arise from specific circumstances, or it may be lifelong.

Course

- As women age, sexual problems other than desire problems tend to decrease, except for hormonally induced lubrication problems.
- The opposite is true for men: As they age, their sexual problems tend to increase, usually because of erectile difficulties that are associated with prostate problems, cardiovascular problems, or other medical causes (Hackett, 2008; Heiman, 2002b).

Gender Differences

- In one study, the most common problems among men were lack of interest, premature orgasm, and performance anxiety.
- Among women the most common problems were failure to achieve orgasm and painful intercourse.

Cultural Differences

- Cultural norms about sexuality affect the extent to which a sexual problem leads to enough distress or relationship difficulties for it to be considered a disorder (Hartley, 2006). For example, Japanese women have a low prevalence of problems with sexual desire, perhaps because Japanese women do not consider no or little sexual desire to be a problem (Kameya, 2001).

Source: Unless otherwise noted, the source for the table material is American Psychiatric Association, 2000.

in Case 11.8. In addition, as women age, decreased desire is probably related to women’s hormonal shift with menopause: Women who have gone through menopause tend to report diminished desire more so than other women (Eplov et al., 2007). In fact, women who enter menopause abruptly and at an earlier age because of the surgical removal of their uterus and ovaries are more likely to report low sexual desire than are their same-age counterparts who have not yet entered menopause (Dennerstein et al., 2006).

In addition, psychological and social factors account for a given woman’s *distress* about decreased desire, and women in different European countries report different levels of distress in response to decreased desire (Graziottin, 2007).

CASE 11.8 ► FROM THE OUTSIDE: Hypoactive Sexual Desire Disorder

Crystal is a 35-year-old married software engineer who is a team leader in a highly competitive company. She works 12-hour days and says she has no time for exercise or relaxation. Her husband is also an engineer. She has been trying to get pregnant for the past 8 months. They have been having scheduled intercourse on the 13th and 15th days of her regular cycle without success. She states that sex seems like work and she just wants to get it over with. When she married 5 years ago, her sex life was satisfying and she had no difficulty with interest or orgasm.

(Candib, cited in Hicks, 2005)

Sexual Aversion Disorder

Another type of desire disorder is **sexual aversion disorder**, whose hallmark is a persistent or recurrent extreme aversion to and avoidance of most genital sexual contact with a partner (see Table 11.5). People with this disorder may have normal desire, interest, and sexual fantasies and may masturbate. However, even the idea of contact with a partner's genitals or of being touched by a partner makes them anxious, like the man in Case 11.9; if such sexual physical contact occurs, they may panic (Kaplan, 1987).

CASE 11.9 ► FROM THE OUTSIDE: Sexual Aversion Disorder

A 33-year-old stockbroker sought treatment because of "impotence." Five months previously, a close male friend had died of a coronary occlusion, and within the following week the patient developed anxiety about his own cardiac status. Whenever his heart beat fast because of exertion, he became anxious that he was about to have a heart attack. He had disturbing dreams from which he would awaken anxious and unable to get back to sleep. He stopped playing tennis and running.

The patient began to avoid sexual intercourse, presumably because of his anxiety about physical exertion. This caused difficulties with his wife, who felt that he was deliberately depriving her of sexual outlets and was also preventing her from becoming pregnant, which she very much desired. In the past month, although no longer worried about his heart, the patient had avoided sexual intercourse entirely. He claimed to have some desire for sex, but when the situation arose, he could not bring himself to do it. He became so upset about his sexual difficulties that he began to have trouble concentrating at work. He felt himself to be a failure both as a husband and as a man. . . .

Four years previously, at 29 and after 3 years of marriage, he had presented himself for treatment with the complaint that he had never attempted to have sexual intercourse with his wife. Sexual activity consisted of his obtaining an erection without either his wife or himself touching his penis, and ejaculation occurred by rubbing his penis on his wife's abdomen. He was unable to touch his wife's genitalia. [He and his wife had treatment at that time, using behavioral techniques discussed below in the treatment section; treatment was a dramatic success.]

(Spitzer et al., 2002, p. 288)

Sexual Arousal Disorders

Sexual arousal disorders occur when a person cannot become aroused or cannot maintain arousal during a sexual encounter. These disorders can arise when the normal progression through the excitement phase is disrupted. This disruption can happen in three ways: (1) when *the pleasurable stimulation gets interrupted* (e.g., when a couple stops their sexual behavior because their young child enters their bedroom), (2) when *other external stimuli interfere* (e.g., when a car alarm goes off outside), or (3) when *internal stimuli interfere* (e.g., when the person becomes anxious, afraid, sad, or angry or has thoughts that intrude) (Malatesta & Adams, 2001).

Like sexual desire, sexual arousal involves neurological and other biological components (responses to stimuli and stimulation), cognitive components (thoughts), and emotional components, including a subjective sense that a response to a particular stimulus is "sexual" (Rosen & Beck, 1988). And any, or any combination, of these components can contribute to the problem. For example, a man

Sexual aversion disorder

A sexual dysfunction characterized by a persistent or recurrent extreme aversion to and avoidance of most genital sexual contact with a partner.

can have an adequate erection but think that he is inadequate because he believes that his penis is not hard enough. Similarly, a woman may respond to the biological sensations of sexual arousal by being afraid of losing control (Malatesta & Adams, 2001). Despite the influence of cognitive and emotional components, the DSM-IV-TR criteria for arousal disorders are exclusively biological (Malatesta & Adams, 2001). They focus on blood flow problems that interfere with sexual arousal.

Female Sexual Arousal Disorder

Two arousal disorders are included in DSM-IV-TR, one for men and one for women. The hallmark of **female sexual arousal disorder** (formerly known as *frigidity*) is persistent or recurrent difficulty attaining or maintaining engorged genital blood vessels in response to adequate stimulation (see Table 11.5). Normally with arousal, some of the fluid in these blood vessels (not the blood itself; Giraldi & Levin, 2006) is exuded into the genital area, serving as a lubricant. With female arousal disorder, however, the less than normal engorgement leads to decreased lubrication.

Menopause can lead to vaginal dryness and inadequate lubrication during sexual activity. In some sense, this makes female sexual arousal disorder a natural part of aging for women. In fact, female arousal disorder is most likely to occur in those who have been through menopause, particularly among women who have adequate sexual desire and can attain orgasm (Heiman, 2002b; Laumann, Paik, & Rosen, 1999). When the arousal problem is not a result of menopause-related hormonal changes, it frequently occurs along with desire and/or orgasm problems; this comorbidity means that it is rare for a woman to have *only* arousal problems that do not arise from hormone-related dryness. Note that DSM-IV-TR focuses exclusively on the neurological and other biological aspect of sexual arousal, not the subjective experience—which may be more significant for many women (Basson et al., 2001; Rosen & Leiblum, 1995).

As with all sexual dysfunctions, the diagnosis of sexual arousal disorder requires that the arousal problem cause distress or relationship difficulties and not be due exclusively to some other psychological disorder or to a medical disorder (see Table 11.5).

Male Erectile Disorder

The hallmark symptom of **male erectile disorder** (*impotence*, in nontechnical language) is a persistent or recurrent inability to attain or maintain an adequate erection until the end of sexual activity (American Psychiatric Association, 2000; see Table 11.5). Some men with male erectile disorder are able to have erections during foreplay but not during actual penetration. Others are not able to obtain a full erection with a new partner or in some situations; still others, such as Harry, in Case 11.10, have the problem during any type of sexual activity. If the man is able to have a full erection during masturbation, biological causes are unlikely. More than half of men over 40 years old have at least some erection problem (Feldman et al., 1994); thus, male erectile disorder, like its counterpart, female arousal disorder, can be seen as a normal by-product of aging. It is estimated that 300 million men worldwide will develop male erectile disorder by the year 2025, in part because of the increased aging of the population (cited in Shabsigh et al., 2003).

Female sexual arousal disorder

A sexual dysfunction marked by a woman's persistent or recurrent difficulty attaining or maintaining engorged genital blood vessels in response to adequate stimulation; formerly referred to as *frigidity*.

Male erectile disorder

A sexual dysfunction characterized by a man's persistent or recurrent inability to attain or maintain an adequate erection until the end of sexual activity; sometimes referred to as *impotence*.

CASE 11.10 ► FROM THE OUTSIDE: Male Erectile Disorder

Harry [had been married for 2 years when] he found out his wife had been involved in numerous extramarital affairs and divorced her. He said his friends all knew but were reluctant to tell him. Following the divorce he encountered erectile problems with all partners—even those to whom he felt close.

(Althof, 2000, p. 261)

Clearly, psychological factors can contribute to male erectile disorder; it is not always a neurological or other biological problem or a consequence of normal aging.

Orgasmic Disorders

An *orgasmic disorder* is diagnosed when a clinician determines that the individual has experienced normal excitement and adequate stimulation for orgasm in normal circumstances (based on the person's age and other factors)—but fails to have an orgasm. If a man or woman cannot achieve orgasm with intercourse but can do so through other types of sexual stimulation, the individual is not necessarily considered to have an orgasmic disorder. Like sexual arousal disorders, DSM-IV-TR includes separate diagnoses for males and for females who have difficulty reaching orgasm: female orgasmic disorder and male orgasmic disorder. A third disorder in this category, called *premature ejaculation*, is characterized by the opposite problem in males—coming to orgasm too quickly, with little stimulation. Disorders in this category may involve neurological (and other biological), cognitive, and emotional components.

Female Orgasmic Disorder

Female orgasmic disorder is diagnosed when a woman's normal sexual excitement does not lead to orgasm or when orgasm is delayed following a normal amount of stimulation (see Table 11.5). Women who experience occasional difficulty achieving orgasm do not have this disorder. The problem with achieving orgasm must be persistent and must exceed what would be expected based on the woman's age and sexual experience. Moreover, the clinician should make sure that the problem with orgasm is not caused by inadequate sexual stimulation. As with all sexual dysfunctions, female orgasmic disorder is only diagnosed if the problem concerning orgasm causes relationship problems or distress. Approximately 5–24% of women may have adequate sexual desire and excitement but nonetheless have female orgasmic disorder (Laumann et al., 1994; Spector & Carey, 1990).

Clinicians distinguish between two types of female orgasmic disorder: absolute and situational. If female orgasmic disorder is *absolute*, the woman does not have an orgasm in any circumstance. If female orgasmic disorder is *situational*, the woman may have an orgasm only in certain circumstances, for example, when masturbating. Lola, described in Case 11.11, has the absolute type of female orgasmic disorder.

CASE 11.11 ► FROM THE OUTSIDE: Female Orgasmic Disorder

Lola, a 25-year-old laboratory technician, has been married to a 32-year-old cabdriver for 5 years. The couple has a 2-year-old son, and the marriage appears harmonious.

The presenting complaint is Lola's lifelong inability to experience orgasm. She has never achieved orgasm, although during sexual activity she has received what should have been sufficient stimulation. She has tried to masturbate, and on many occasions her husband has manually stimulated her patiently for lengthy periods of time. Although she does not reach climax, she is strongly attached to her husband, feels erotic pleasure during lovemaking, and lubricates copiously. According to both of them, the husband has no sexual difficulty.

Exploration of her thoughts as she nears orgasm reveals a vague sense of dread of some undefined disaster. More generally, she is anxious about losing control over her emotions, which she normally keeps closely in check. She is particularly uncomfortable about expressing any anger or hostility.

(Spitzer et al., 2002, pp. 238–239)

Male Orgasmic Disorder

Male orgasmic disorder is a delay or absence of orgasm in men; Table 11.5 lists the specific criteria. Male orgasmic disorder is different from female orgasmic disorder in several respects: (1) Male orgasmic disorder typically involves problems reaching orgasm with a partner, even though the man can easily reach orgasm during masturbation (Apfelbaum, 1989, 2000); (2) male orgasmic disorder typically involves problems with orgasm only during vaginal intercourse (some men, however, cannot

Female orgasmic disorder

A sexual dysfunction characterized by a woman's persistent problem in progressing from normal sexual excitement to orgasm, such that orgasm is delayed or does not occur, despite a normal amount of appropriate stimulation.

Male orgasmic disorder

A sexual dysfunction characterized by a man's delay or absence of orgasm.

ever reach orgasm); and (3) its prevalence (less than 10% of the general male population) is lower than that of female orgasmic disorder (Spector & Carey, 1990).

Men with orgasmic disorder—particularly those who only have difficulty achieving orgasm with vaginal intercourse—do not necessarily seek treatment because couples may not view it as a significant problem; both partners may come to orgasm, although the man may do so through sexual activities other than vaginal intercourse, as the man in Case 11.12 does. Usually what brings men with this sexual dysfunction to seek treatment is the desire to have a baby, at which point male orgasm during vaginal intercourse becomes necessary.

CASE 11.12 ► FROM THE OUTSIDE: Male Orgasmic Disorder

[A man, 43 and never married, had sexual relationships with many women and was proud that he could sustain erections for a long time.] He nevertheless found masturbation more satisfying and had never come close to [having an orgasm during vaginal intercourse.] He had only reached orgasm four times with a partner, all with the same partner, by masturbating and then switching to fellatio only at the point of ejaculatory inevitability. . . . He was afraid that if he reached orgasm [during vaginal intercourse], he would be “under a woman’s dominion.”

(Apfelbaum, 2000, pp. 236–237)

Premature Ejaculation

A second type of orgasm-related problem for men is **premature ejaculation**, which is characterized by orgasm and ejaculation that occur earlier than the man expects—usually before, immediately during, or shortly after penetration (American Psychiatric Association, 2000; see Table 11.5 for the diagnostic criteria). Criterion A in Table 11.5 uses the phrase “minimal sexual stimulation” to indicate that the man ejaculates after less intense or briefer stimulation than would normally result in orgasm. Premature ejaculation is the most common male sexual dysfunction (Hellstrom et al., 2006; Laumann, Paik, & Rosen, 1999; Spector & Carey, 1990). According to Masters and Johnson (1970), premature ejaculation occurs when the man is unable to control his ejaculation sufficiently to satisfy his partner at least 50% of the time. Another definition is that premature ejaculation occurs when the man cannot voluntarily delay the ejaculation reflex (Kaplan, 1981).

Premature ejaculation is considered by some to be a *couple’s* problem, as with Mr. and Mrs. Albert in Case 11.13. That is, it is a problem only insofar as the couple prefers the man to ejaculate in a particular phase of his partner’s sexual response cycle: Some couples try to have both partners achieve orgasm at around the same time, but this is difficult with premature ejaculation. Other couples do not find early ejaculation a problem: The partner is sexually stimulated to orgasm in other ways after the man ejaculates (Malatesta & Adams, 2001).

CASE 11.13 ► FROM THE OUTSIDE: Premature Ejaculation

Mr. and Ms. Albert are an attractive, gregarious couple, married for 15 years, who [are in] the midst of a crisis over their sexual problems. Mr. Albert, a successful restaurateur, is 38. Ms. Albert, who since marriage has devoted herself to child rearing and managing the home, is 35. She reports that throughout their marriage she has been extremely frustrated because sex has “always been hopeless for us.” She is now seriously considering leaving her husband.

The difficulty is the husband’s rapid ejaculation. Whenever any lovemaking is attempted, Mr. Albert becomes anxious, moves quickly toward intercourse, and reaches orgasm either immediately upon entering his wife’s vagina or within one or two strokes. He then feels humiliated and recognizes his wife’s dissatisfaction, and they both lapse into silent suffering. He has severe feelings of inadequacy and guilt, and she experiences a mixture of frustration and resentment toward his “ineptness and lack of concern.” Recently, they have developed a pattern of avoiding sex, which leaves them both frustrated, but which keeps overt hostility to a minimum. . . . [Mr. Albert’s] inability to control his ejaculation is a source of intense shame, and he finds himself unable to talk to his wife about his sexual “failures.” Ms. Albert is highly

Premature ejaculation

A sexual dysfunction characterized by orgasm and ejaculation that occur earlier than the man expects, usually before, immediately during, or shortly after penetration.

sexual and easily aroused in foreplay but has always felt that intercourse is the only “acceptable” way to reach orgasm.

In other areas of their marriage, including rearing of their two children, managing the family restaurant, and socializing with friends, the Alberts are highly compatible. Despite these strong points, however, they are near separation because of the tension produced by their mutual sexual disappointment.

(Spitzer et al., 2002, pp. 266–267)

Sexual Pain Disorders

Some people experience significant pain with sexual activity, particularly with sexual intercourse. DSM-IV-TR specifies two sexual dysfunctions that are related to consistent pain associated with sexual intercourse, dyspareunia and vaginismus, which are discussed in the following sections.

Dyspareunia

Dyspareunia is characterized by recurrent or persistent genital pain that is associated with sexual intercourse (see Table 11.5). In men, dyspareunia is rare (Bancroft, 1989; Sadock, 1995). When it does occur in men, the pain occurs after ejaculation and is often related to a medical condition. Up to 10–20% of women have dyspareunia (Laumann, Paik, & Rosen, 1999; Rosen et al., 1993). In women, dyspareunia may be related to a physical condition, such as surgical scar tissue or infection, or to insufficient lubrication, as can occur with menopause. When the pain persists, it can lead to problems with desire or excitement.

Vaginismus

Vaginismus consists of recurrent or persistent involuntary spasms of the musculature of the outer third of the vagina, which interfere with sexual intercourse (American Psychiatric Association, 2000; see Table 11.5). These spasms may be so strong that it is impossible to insert the penis into the vagina, or at least not without significant discomfort. Such spasms may also occur when trying to insert a tampon, finger, or *speculum* (the device inserted vaginally during a pelvic medical examination). This difficulty can lead some women to become afraid of any type of vaginal penetration. A fear of penetration related to vaginismus is distinguished from sexual aversion: With vaginismus, the woman only avoids sexual activities that involve vaginal insertion, not all sexual activities.

Most women with vaginismus also have dyspareunia (Heiman, 2002b). Dyspareunia can make vaginismus worse as a woman tenses certain vaginal muscles when she anticipates intercourse (Carey & Gordon, 1995; Tollison & Adams, 1979). Although vaginismus can lead to problems in the desire phase or excitement phase of the sexual response cycle, it typically does not (Kolodny, Masters, & Johnson, 1979). Further, other forms of sexual stimulation are usually satisfying. As with premature ejaculation, the desire to become pregnant is the most common reason why women with vaginismus seek treatment (Leiblum, Pervin, & Campbell, 1989). Like most women with vaginismus, Lynn in Case 11.14 also has dyspareunia.

CASE 11.14 ► FROM THE INSIDE: LYNN Vaginismus and Dyspareunia

We’ve been married for nine years and have two great kids. Unfortunately, family responsibilities and high stress jobs really cut into our together time. Exhaustion makes sex seem like an extra chore—just one more thing to do that we don’t have time to enjoy and now can’t. I don’t know if it’s from the busy, stressful lifestyle or not, or from being “out of practice,” but about a year ago intercourse began to really hurt. It started with a burning sensation some of the time during sex. I found myself getting more anxious that it would hurt again and it usually did. Trips to the doctor revealed little besides the standard “do more foreplay or use more lubricant” advice. Now it seems like my body just “tightens up” and we can hardly have sex at all. Entry is painful and besides burning I feel tightness, spasms, discomfort and anxiety. The

continued on next page

Dyspareunia

A sexual dysfunction characterized by recurrent or persistent genital pain that is associated with sexual intercourse.

Vaginismus

A sexual dysfunction in females in which recurrent or persistent involuntary spasms of the musculature of the outer third of the vagina interfere with sexual intercourse.

pleasure is gone, and there is only the expectation of discomfort and frustration. Our marriage is suffering and it feels like a deep chasm is growing between us as sex has become impossible. My husband and I fight a lot more and I know he is growing impatient. I don't want my children to be another statistic of divorce because of this. I just don't know what to do.

(Vaginismus.com, 2007)

Criticisms of the Sexual Dysfunctions in DSM-IV-TR

Criticisms of the DSM-IV-TR classification of and criteria for sexual dysfunctions focus on several issues:

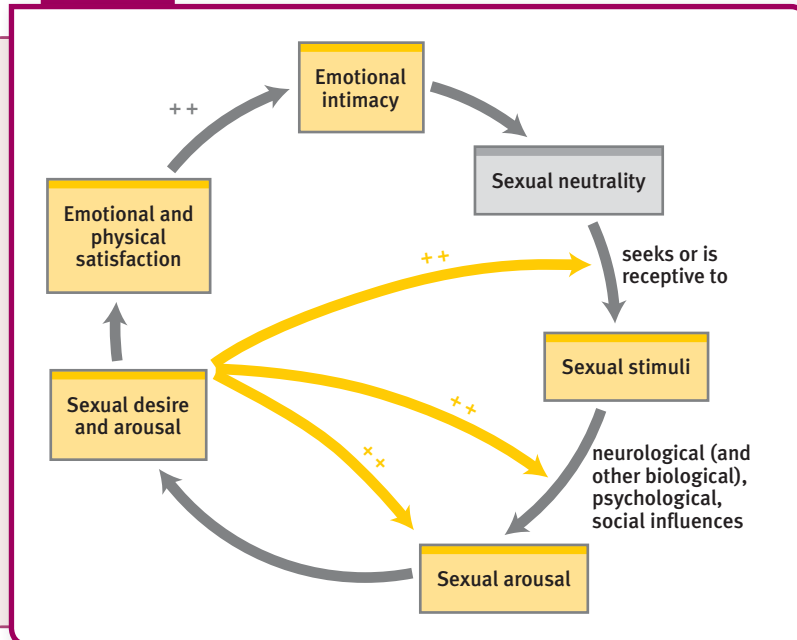

1. The sexual dysfunctions are based on the lock-step, sequential progression in Masters and Johnson's model of the sexual response cycle. However, this may not be the best model for understanding sexual dysfunctions in women. As shown in Figure 11.3, for women, arousal and desire often occur at the same time, or arousal can lead to desire rather than desire always preceding arousal. In this alternative model for females, emotional and physical satisfaction may include orgasm, although not all women need to have an orgasm to feel satisfied.

Figure 11.3

11.3 ► An Alternative Female Sexual Response Cycle

An alternative model of the female sexual response cycle (Basson, 2001)—in the context of relationships—is analogous to a circle. The cycle starts with sexual neutrality: not feeling very sexual, but with an openness to seek or be receptive to sexual stimuli. In turn, such sexual stimuli may, depending on neurological (and other biological), psychological, and social factors operating at that moment, lead to sexual arousal, which in turn leads to a sense of desire and further arousal. The desire creates positive feedback loops (++) that lead to heightened arousal, which then leads to emotional and physical satisfaction. This satisfaction in turn produces a sense of emotional intimacy with her partner, making her more likely to be receptive to or seek out sexual stimuli in the future. She may also feel spontaneous sexual desire, which leads to positive feedback loops among the first three phases.

Source: Adapted from Basson, 2001. For more information see the Permissions section.

2. DSM-IV-TR focuses on body parts (heart rate, genital engorgement) rather than the whole person (Apfelbaum, 2000; Kleinplatz, 2001). Psychological and social factors—such as the subjective experience, thoughts and feelings, the quality of the relationship with the partner and the interaction of the couple, and the context of sexual activity—are generally overlooked (Tiefer, 1991). These factors play a larger role for women than is recognized by the DSM-IV-TR criteria (Basson, 2005; Basson et al., 2004, 2005).
3. The emphasis is on orgasm as the conclusion of sexual activity (Tiefer, 1991). Sexual activity that does not end in orgasm is implicitly considered not satisfying (Kleinplatz, 2001). Nevertheless, as noted above, some women feel satisfied even without having an orgasm.
4. The DSM-IV-TR criteria rest on a cultural definition of “normal” to define abnormal sexual functioning (Moynihan, 2003). Critics note that the norm promoted by American culture is that of an adolescent male, ever ready for

sexual encounters, and able to have erections on demand (Kleinplatz, 2001). As women and men age, they are more likely to meet the criteria for a sexual dysfunction even when there is no real “dysfunction”—only the body’s growing older (Tiefer, 1987, 1991).

5. The criteria do not include any specific duration; people with symptoms that are transient, perhaps as a result of the aftereffects of surgery or a difficult time in a relationship, are grouped together with people whose symptoms are chronic (Balo, Segraves, & Clayton, 2007).
6. The DSM-IV-TR definitions of various sexual dysfunctions for women are not necessarily the ones used by those who specialize in the field of human sexuality (Basson, 2001).
7. Hypoactive sexual desire disorder in particular has been criticized on several grounds (Basson, 2001). First, it is left to the clinician to determine whether desire is sufficiently lacking (accounting for the individual’s age and the context of the problem), and clinicians from diverse cultural and religious or spiritual backgrounds differ in their assessments. Second, the DSM-IV-TR criteria can lead to the diagnosis of a sexual dysfunction when there may be no actual dysfunction, but rather the couple may have a *discrepancy* in desire, where one partner desires sexual relations more or less often than the other (Rosen & Leiblum, 1989). In fact, diminished sexual desire may be an appropriate response to a relationship that isn’t functioning well (Basson et al., 2001). Finally, different types of problems with desire (such as lifelong versus acquired or situational versus generalized) may require different treatments. Nevertheless, DSM-IV-TR clumps all variations of hypoactive sexual desire disorder together (Heiman, 2002a).
8. Many researchers in the field believe that dyspareunia should not be considered a *sexual* disorder, but rather a type of *pain* disorder (Binik, 2005; Binik et al., 2002).

Understanding Sexual Dysfunctions

In a sense, we can view Laura’s lack of sexual desire as being related, at least in part, to Mike’s sexual difficulties: As Mike pulled back from Laura, Laura’s desire for sexual intimacy with Mike waned. Their experiences highlight the fact that sexuality does not exist in a vacuum. Sexuality and any problems related to it develop through feedback loops among neurological (and other biological), psychological, and social factors.

Neurological and Other Biological Factors

In this section, we first consider how disease, illness, surgery, and medication can, directly and indirectly, disrupt normal sexuality. We then turn to the effects of normal aging, which can produce sexual difficulties.

Sexual Side Effects: Disease, Illness, Surgery, and Medication

Disease or illness can produce sexual dysfunction directly, as occurs with prostate cancer or cervical cancer. In addition, surgery can lead to sexual problems: Half of women who survive major surgeries for gynecological-related cancer develop sexual difficulties that do not become better over time (Andersen, Andersen, & DeProse, 1989).

Disease or illness can also cause side effects of sexual dysfunction *indirectly*, as occurs with diabetes or circulation problems that limit blood flow to genital areas. Some physical problems can lead to sexual problems even more indirectly: People who have had a heart attack may be afraid to engage in sexual activity for fear that it will bring on another attack.

When a relationship has significant problems, a lack of sexual desire may be appropriate and not a sign of a disorder.

Rob Wilkinson/Alamy

Richard Price/Getty Images

Prolonged bike riding can sometimes crush the nerves and arteries to the penis or clitoris, leading to arousal problems.

Some medications can interfere with normal sexual response, including:

- SSRIs and other dopamine-blocking medications such as traditional anti-psychotics,
- beta-blockers and other medications that treat high blood pressure,
- antiseizure medication,
- estrogen and progesterone medications,
- HIV medications, and
- narcotics and sedative-hypnotics.

Alcohol can also disrupt the normal sexual response cycle.

Aging

Researchers have found that normal aging can affect sexual functioning among older people (George & Weiler, 1981). For instance, as we've seen, older women often have a vaginal lubrication problem that arise with menopause; when the lubrication problem is not addressed (for instance, with an over-the-counter lubricant such as Astroglide or K-Y Jelly), the dryness can cause intercourse to be painful and lead to dyspareunia.

In addition, as men age, their testosterone levels decrease significantly, often making prolonged tactile stimulation necessary to attain erections. Older men are likely to experience reduced penile hardness, decreased urgency to reach climax, and a longer refractory period (Butler & Lewis, 2002; Masters & Johnson, 1966).

In addition to the normal biological changes that arise with age, older people of both sexes may develop illnesses or diseases that make sexual activity physically more challenging. They also may take medications that have side effects that interfere with their sexual response. However, most older people say that they continue to enjoy sex.

Psychological Factors: Predisposing, Precipitating, and Maintaining Sexual Dysfunctions

Certain beliefs and experiences can *predispose* individuals to develop sexual dysfunctions (see Table 11.7). For example, a woman may believe that women in general lose their sexual desire as they age and a man may believe that “real men” have intercourse twice a day and that only rock-hard erections will satisfy women (Nobre & Pinto-Gouveia, 2006). Such a belief can lead to a self-fulfilling prophecy, if the belief produces the perception of a dysfunction and that perception in turn leads to a real dysfunction. For example, a man who believes that women are only

Nick Daly/Jupiter Images

Men and women often experience changes in aspects of sexual performance as they get older, which may disrupt sexual activity. However, most will still experience pleasure from sexual activities (Leiblum & Seagraves, 2000).

Table 11.7 ▶ Predisposing Events for Sexual Dysfunctions

Event	Effect
The view that sex is dirty and sinful	Early learning of such negative attitudes toward sex and misinformation leads to fears and inhibitions, which can lead to problems of desire, arousal, orgasm, and vaginismus.
Early negative conditioning experiences	In men, premature ejaculation can develop after hurrying to have an orgasm quickly for fear of being “caught.” In women, a fear of pregnancy or being “caught” can lead to anxiety that contributes to sexual dysfunction.
Sexual trauma	Sexual trauma can produce negative conditioning and can lead to a fear of sex, as well as arousal and desire problems.

Sources: Bartoi & Kinder, 1998; Becker & Kaplan, 1991; Kaplan, 1981; Laumann, Paik, & Rosen, 1999; LoPiccolo & Friedman, 1988; Masters & Johnson, 1970; Silverstein, 1989.

satisfied by very hard erections may develop a problem as he ages: He may notice that his erections are not as hard as they were when he was younger and then become self-conscious and preoccupied during sex, which does in fact lead him to fail to satisfy his partner.

In addition, having been sexually abused as a child also predisposes a person later to develop sexual dysfunctions. Consider the fact that male victims of childhood sexual abuse are three times more likely to have erection problems and twice as likely to have desire problems and premature ejaculation than their peers who did not experience childhood sexual abuse (Laumann, Paik, & Rosen, 1999). Similarly, women who were victims of childhood sexual abuse are more likely than women who were not abused to report sexual problems (although not necessarily problems that meet the DSM-IV-TR criteria for sexual dysfunctions; Westerlund, 1992).

Factors that are thought to *precipitate*, or trigger, sexual dysfunctions generally involve sexual situations in which an individual feels anxious—for example, situations in which a man becomes nervous about not “performing” adequately. Such preoccupations can lead to disorders of sexual desire and arousal. Here are some examples of different types of problematic preoccupations:

- focusing attention on sex-related fears and worries, which distract and detract during a sexual encounter;
- feeling uncomfortable with how one’s body may look or feel to a partner (Berman & Berman, 2001); and
- worrying about nonsexual matters, such as work or family problems.

Once someone has a problem with desire, arousal, or orgasm, he or she may become anxious that it will happen again, which sets up a self-fulfilling prophecy and becomes a *maintaining factor*. For instance, when a single sexual experience was perceived as a “failure,” an individual may become anxious during subsequent sexual experiences, monitoring his or her responsiveness (and so *thinking* about the sexual response rather than *experiencing* it)—which in turn can interfere with a normal sexual response and create a sexual dysfunction (Bach, Brown, & Barlow, 1999).

Social Factors

Although sexuality involves how we see ourselves, it usually also involves other people. The sexual relations of a couple are influenced by how the partners relate to each other, specifically: (1) how conflict is expressed and resolved, (2) how they communicate their needs and desires, their likes and dislikes, (3) how they handle stress, and (4) how strongly attracted they each are to each other (Tiefer, 2001). For example, Mike’s sexual secret from Laura led him to pull away from her sexually. She thought he wasn’t interested in sex. That is, from her vantage point, he appeared to have a sexual desire problem, and she herself then lost interest.

FEEDBACK LOOPS IN ACTION: Sexual Dysfunctions

Just as neurological, psychological, and social factors influence each other and contribute to a normal sexual response, feedback loops among these factors can contribute to sexual dysfunctions (see Figure 11.4). Such feedback loops best explain why some people, and not others, develop sexual dysfunctions. For instance, people’s sexual beliefs (“My body looks ugly” or “I won’t be able to have an orgasm”; psychological factors) can influence their sexual functioning: The beliefs create fears

Jeff Greenberg/Photo Edit

Justin Pumfrey/Getty Images

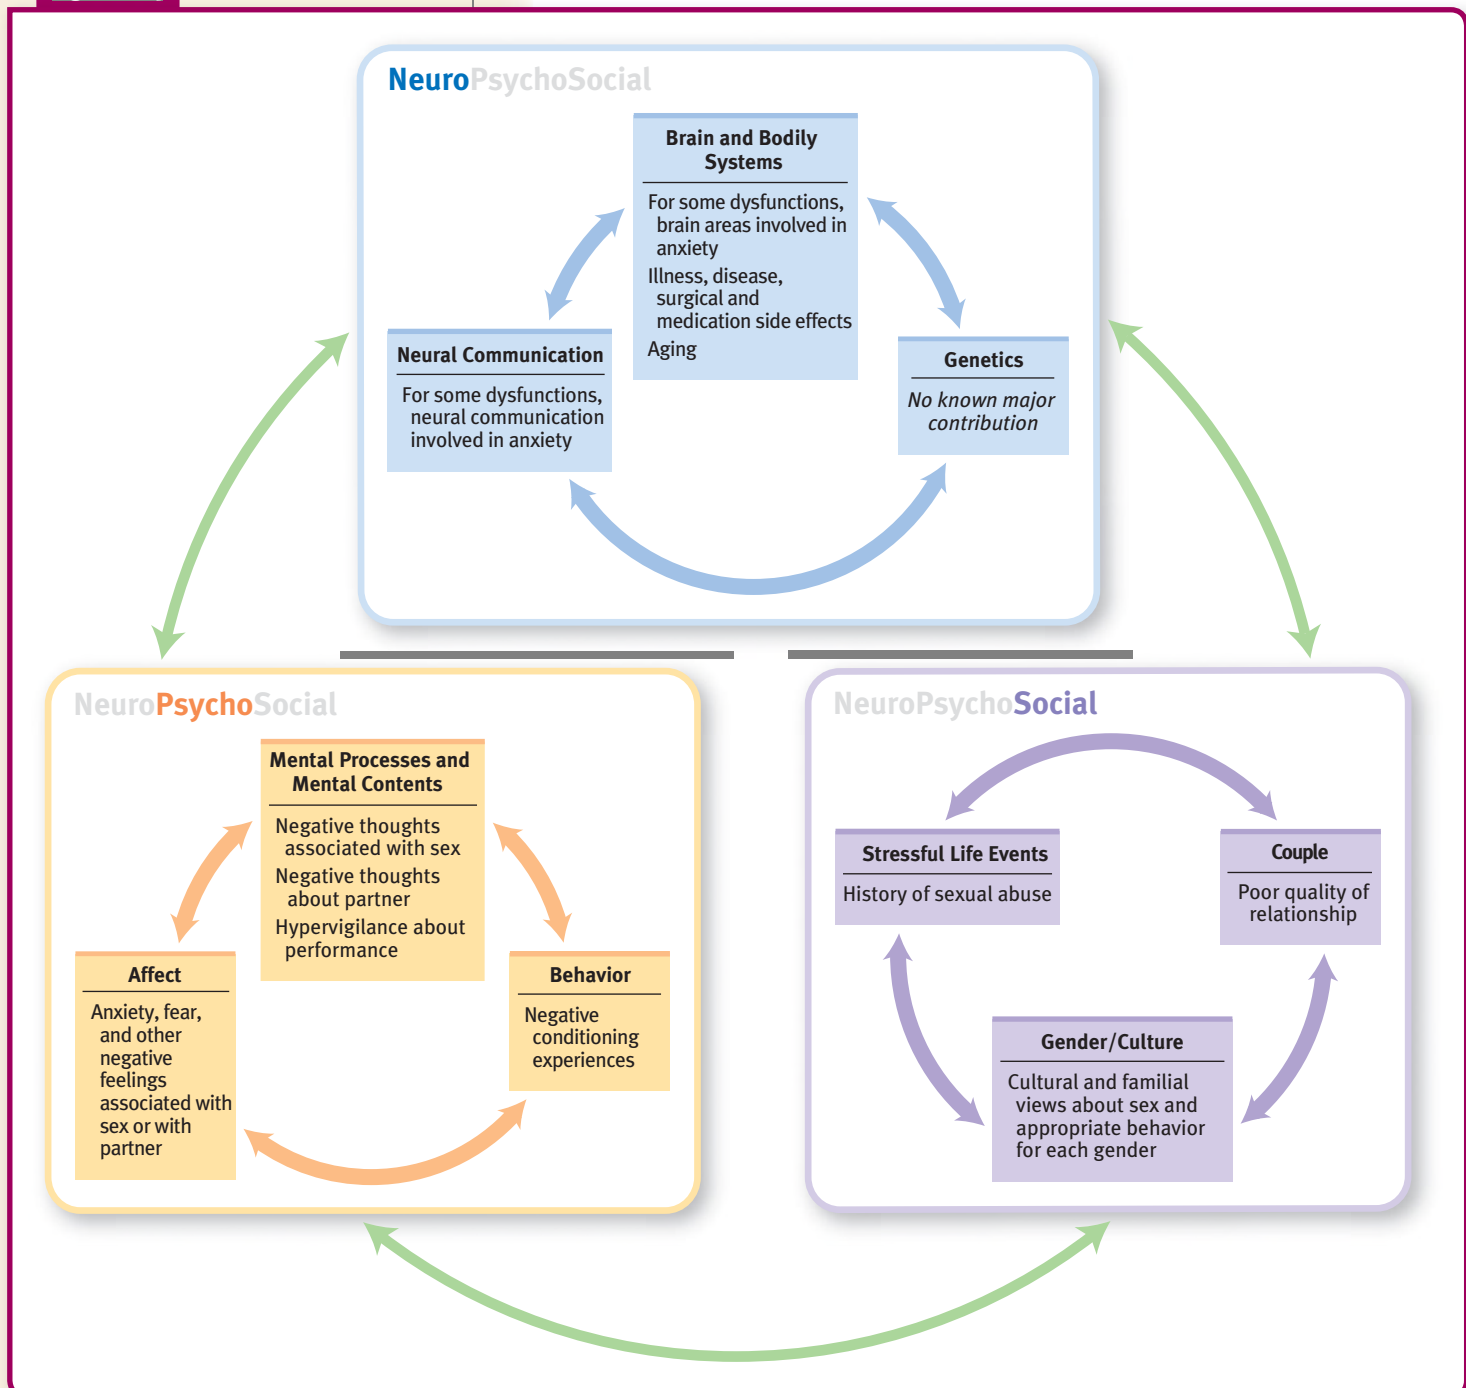

Being chronically preoccupied and anxious about something—including how your body might look or feel to a partner—while engaged in sexual activity can interfere with the normal sexual response cycle, and lead to a sexual dysfunction.

and anxieties that can lead to high levels of sympathetic nervous system activity (neurological factor), which physically interferes with sexual arousal and orgasm (Apfelbaum, 2001; Kaplan, 1981; Masters & Johnson, 1970). Current problems in a relationship (social factors) similarly affect sexual functioning, as can having been sexually abused (Bartoi & Kinder, 1998; Becker, 1989; DiLillo, 2001; Laumann, Paik, & Rosen, 1999).

Familial and cultural views of sexuality (social factors) can also influence sexual functioning (psychological and neurological factors): We are all taught various lessons about sexuality both directly (what our parents, teachers, religious leaders, and

Figure 11.4

peers told us) and indirectly (through observations of family members or friends and from television, movies, books, and the Internet). Some people are taught that sexual relations outside of marriage are wrong, whereas other people are taught that sexual experimentation before marriage is a good thing. Such direct and indirect lessons help shape each person's notion of appropriate or normal sexuality. Depending on what an individual learned about sex, he or she may be primed to have sexual difficulties in some situations.

The interplay of factors is seen in the contrasting examples of two men, each of whom has an experience of erectile dysfunction. One man has a history of poor self-esteem and worry (psychological factors), as well as anxiety about his sexual performance (neurological and psychological factors). Although he is very attracted to his partner and generally has a positive view of sex (psychological and social factors), he worries that his partner may get annoyed at his “performance failure” and perhaps leave him. This leads him to be even more anxious the next time they have a sexual encounter (neurological and social factors), and he again has difficulty attaining or maintaining an erection, and thus develops persistent erectile dysfunction. In contrast, the other man, who also has a positive attitude toward sex and is attracted to his partner, drinks too much—which leads to an episode of erectile dysfunction. However, this man does not have the general “performance” worries of the first man, nor is he anxious about how his partner may respond. He expects (psychological factor) later to have his usual erections and to be able to satisfy his partner, which is in fact what happens.

Thus, neurological, psychological, and social factors influence each other in complex ways that predispose an individual to develop a sexual dysfunction, and that precipitate and maintain it once it develops.

Assessing Sexual Dysfunctions

Many people first seek help for sexual problems from a physician, who may investigate the extent to which medical factors—rather than psychological or social factors—contribute to the problems. A physician, in turn, may refer the patient to a specialist. Patients may see a *sex therapist*—usually a mental health clinician—trained to assess and treat problems related to sexuality and sexual activity. Before sex therapists begin to treat people for sexual dysfunctions, they usually make sure that the patients have a thorough assessment to identify specific factors that contribute to the dysfunction. The results of the assessment guide which factor(s) are targeted for treatment and which specific treatments the therapist suggests. Sexual dysfunctions can be assessed by examining neurological and other biological factors, as well as psychological and social factors.

Assessing Neurological and Other Biological Factors

Mental health professionals who assess and treat sexual problems want to know about an individual's health status and sexual response cycle. Such information may be obtained through lab tests that measure endocrine and hormone levels, ultrasound imaging to assess internal organs, and tests to assess the functioning of sensory nerves. Testing for men may include a plethysmograph to assess penile response, and testing for women may include vaginal probes to measure lubrication and the vagina's ability to relax and dilate. Genital swelling and lubrication—or their lack—in a woman do not necessarily reflect her subjective sense of sexual arousal or pleasure (Basson, 2005).

Assessing Psychological Factors

An assessment by a sex therapist may include personality tests and inventories such as the MMPI-2 (see Chapter 3), as well as questions about symptoms of depression (which can lead to problems of sexual desire). In addition, the sex therapist will assess the patient's thoughts, feelings, and expectations regarding his or her partner and about sexual activity, as well as past masturbatory and other sexual experiences

that might bear on the current difficulties. This information helps the sex therapist determine what specific psychological factors contribute to the patient's sexual dysfunction. For example, Lola in Case 11.11 was concerned about losing control during orgasm, and the man in Case 11.12 was afraid that he'd be "under a woman's dominion" if he had orgasm during vaginal intercourse.

Assessing Social Factors

A sex therapist investigates how relationship issues affect a patient's sexuality and whether the sexual difficulties occur only with the patient's partner or more generally. For instance, the therapist might ask what function sex serves in the relationship and how unresolved conflict and power issues affect the sexual aspect of the relationship (Stock & Moser, 2001). Other questions might address how the couple decides on the timing, duration, or specific activities of sexual relations. Depending on the answers, the sex therapist may target specific social factors as part of the treatment.

Treating Sexual Dysfunctions

Once the specific nature of the sexual problem has been determined, treatment can target the relevant factors. Depending on the nature of the problem and the types of treatments the patient—and his or her partner—are interested in, treatment may include medication, cognitive-behavioral therapy, sex therapy (which may provide specific guidance and techniques to treat sexual problems), couples therapy, or some other type of therapy.

Targeting Neurological and Other Biological Factors: Medications

There has been an increasing trend toward the *medicalization* of sex therapy, that is, a tendency to target neurological and other biological factors (see Table 11.8) and pay less attention to other factors. In the 1990s, medical treatments for erectile dysfunction began in earnest with the advent of the drug Viagra and the marketing campaign for it, which brought the topic of erectile dysfunction from a rarely discussed but relatively common problem among older men to a topic of everyday conversation. Viagra (*sildenafil citrate*) is one of the class of drugs called *phosphodiesterase type 5 inhibitors*, or *PDE-5 inhibitors*. Viagra doesn't cause an erection directly; instead, the drug operates by increasing the flow of blood to the penis only when a man is sexually excited. Viagra (and its competitors, such as Cialis) is not a cure but a treatment for impotence, and it is effective only if the man takes a pill before sexual activity.

Table 11.8 ▶ Medications for Sexual Dysfunctions

Sexual phase	Female	Male
Desire	<i>Hypoactive sexual desire disorder</i> : Testosterone pills or cream; Wellbutrin (<i>bupropion</i>) may counteract diminished desire that is a side effect of SSRIs taken for another disorder <i>Sexual aversion disorder</i> : Antianxiety medication for the phobia or panic component	
Arousal	<i>Female sexual arousal disorder</i> : PDE-5 inhibitors when arousal problems have a medical cause	<i>Erectile disorder</i> : PDE-5 inhibitors
Orgasm		<i>Premature ejaculation</i> : SSRIs
Pain	<i>Vaginismus</i> : Antianxiety medication <i>Dyspareunia</i> : Estrogen cream	

Some women with arousal disorders use PDE-5 inhibitors because these medications have an analogous effect on the clitoris. However, PDE-5 inhibitors are most effective with women who—for medical reasons—have reduced blood flow to the clitoral area, which leads to decreased physical arousal (Berman et al., 2001). Critics point out that prescribing this type of medication for a woman will not improve sexual functioning when the problem is with her relationship, not her body (Bancroft, 2002).

At least in some cases, PDE-5 inhibitors (and the medicalization of treatment more generally) may actually produce sexual problems. For example, consider a middle-aged man with erectile dysfunction who is given Viagra and resumes sexual intercourse with his postmenopausal wife. However, his wife cannot maintain adequate lubrication or interest during intercourse given her husband's (now) extended erections. In this situation, according to DSM-IV-TR, she may be viewed as having sexual arousal disorder, but this “disorder” may only exist because her partner is taking medication to counter effects of aging. Many researchers and clinicians maintain that in such cases the woman does not have a disorder, although she may have a relationship problem (Basson et al., 2001).

Targeting Psychological Factors: Shifting Thoughts, Learning New Sexual Behaviors

Two types of treatment directly target psychological factors: *Sex therapy*, which provides specific guidance and techniques to treat sexual problems, and psychological therapies—such as CBT or psychodynamic therapy—which address feelings and thoughts about oneself and others and how they may relate to sexual problems.

One of the main goals of treatments that directly target psychological factors related to sexual dysfunctions is to educate patients about sexuality and the human sexual response. Another goal is to help patients develop strategies to counter negative thoughts, beliefs, or attitudes that may interfere with sexual desire, arousal, or orgasm (Carey & Gordon, 1995). For instance, during sexual activity, some people are preoccupied with nonsexual thoughts that prevent them from reaching full arousal or orgasm. These nonsexual thoughts might be work-related worries, thoughts about household tasks that need to be done, or worries that someone will interrupt the sexual encounter. Cognitive treatment may involve teaching a patient how to filter out such thoughts and (re)focus on the sexual interaction. The therapist might encourage the patient to apply standard cognitive methods (see Chapter 4) to sexual encounters, such as problem solving (“You could turn the phone off”) or cognitive restructuring (“Are you likely to think of a solution to your work problem while making love? If not, you can let your mind focus on the physical sensations you are experiencing”).

In addition to addressing very specific sex-related thoughts and feelings, the treatment may also address the patient's view of himself or herself. Sometimes the sense of being dysfunctional or inadequate generalizes from the sexual realm to the whole self, and the individual with a sexual dysfunction comes to have low self-esteem and self-doubts generally. In such cases, the therapy may use cognitive and behavioral methods (see Chapter 4), to address the thoughts and feelings of being inadequate in multiple spheres of life.

Behavioral treatment typically involves “homework.” Depending on the nature of the problem, the homework may be completed by the patient or by the patient and his or her partner together. Homework for women with female orgasmic disorder (as well as other sexual dysfunctions) may include masturbation in order to learn more about what sensations and fantasies facilitate arousal and orgasm (Meston et al., 2004). For many patients, a first step is to begin to (re)discover pleasurable sensations through specific homework exercises. In the beginning of behavioral treatment, homework may include **sensate focus exercises**, which are designed to increase awareness of pleasurable sensations, but preclude orgasm. Such exercises may prohibit genital touching, intercourse, or orgasm; rather partners take turns touching other parts of each others' bodies so that each can discover what kinds of stimulation feel most enjoyable (Baucom et al., 1998; LoPiccolo & Stock, 1986).

Sensate focus exercises

A behavioral technique that is assigned as homework in sex therapy, in which an individual or couple seeks to increase awareness of pleasurable sensations that do not involve genital touching, intercourse, or orgasm.

Sex therapists may recommend sensate focus exercises—a graduated series of tasks that focus on body awareness and sexual sensations. One such task might be a sensual bath, either alone or with a partner; the goal is not to come to orgasm but rather to become aware of pleasurable sensations.

Comstock/Punchstock

Typically, the therapist explains a homework assignment during a session, and the patient or couple reports the results during the following session. The goals of behavioral techniques are to help patients develop a more relaxed awareness of their bodies and increase their orgasmic responding and control. Treatment may also involve a realistic look at an individual's or couple's daily work schedule, which is followed by a discussion of how to create the time and energy to begin a sexual encounter so that the partners are not tired or busy. In addition, therapists typically use specific behavioral techniques for different sexual dysfunctions. For instance, people with sexual aversion disorder may undergo desensitization as part of their treatment, gradually exposing themselves to frightening or aversive elements of the sexual situation (Kaplan, 1995).

Researchers have examined how well specific psychosocial treatments (that is, treatments that directly target psychological and social factors) help people with particular sexual disorders. For erectile dysfunction, treatments such as psychoeducation and behavioral homework assignments (such as increasing communication skills) can help to increase satisfaction with erectile functioning, sexual frequency, and satisfaction with the relationship (Heiman & Meston, 1997). Premature ejaculation is significantly helped by behavioral techniques (de Carufel & Trudel, 2006), such as the *squeeze technique* (Kaplan, 1989): Right before ejaculation, the man squeezes the base of the tip (just below the head) of his erect penis for about 4 seconds. When he feels his ejaculation to be under control, he begins stimulation again. Once he has mastered this technique during masturbation, he tries sexual relations with his partner; if necessary for control, he can employ the squeeze technique during sexual relations with his partner (Heiman & Meston, 1997).

Women with vaginismus may be helped by systematic desensitization, which involves gradual dilation of the vaginal opening until vaginal spasms no longer occur. Biofeedback may be helpful for some women with dyspareunia.

For orgasmic disorders, treatments that target psychological factors are more effective for people who have never experienced orgasm; people who have infrequent orgasms, or situational problems achieving orgasm, may be better treated by methods that target the couple's interactions or biological problems (depending on the specific reason for the inconsistency of orgasms; Heiman, 2000). Unfortunately, there are, as yet, few well-designed studies that have assessed specific psychosocial treatments for women's sexual dysfunctions (Heiman, 2002a) in part because research on these treatments is not sponsored by an industry (as is research on the effectiveness of medications).

Targeting Social Factors: Couples Therapy

The sex therapy techniques discussed in the previous section may be implemented alone (by the individual with a sexual dysfunction) or with a partner. Sex therapy may involve teaching couples specific cognitive and behavioral techniques. However, implementing such techniques with a partner requires motivation and willingness to be open with the partner about sexual matters and to experiment sexually. Moreover, how a couple interacts sexually occurs against the backdrop of their overall relationship. Treatment may focus on the couple's relationship issues (couples therapy, rather than sex therapy per se) and include teaching communication, intimacy, and relationship skills (Baucom et al., 1998; Beck, 1995; Heiman, 2002b; Masters & Johnson, 1970), such as assertiveness, problem solving, negotiation, and conflict management (Malatesta & Adams, 2001). Couples therapy may also address issues of power, control, and lifestyle as they relate to the sexual dysfunction; for example, the therapist may employ techniques from systems therapy (see Chapter 4) to focus on assertiveness within the sexual aspects of the relationship. Treatment for a sexual dysfunction in a partner of a lesbian or gay couple may also address special issues that affect their sexual relationship, such as living "in the closet" or sexual intimacy when one partner is HIV positive (Nichols, 2000).

FEEDBACK LOOPS IN TREATMENT: Sexual Dysfunctions

Like successful treatment for any psychological disorder, successful treatment of sexual dysfunctions ultimately affects all the neuropsychosocial factors (see Figure 11.5). For instance, CBT for female orgasmic disorder targets psychological factors (the thoughts, beliefs, and feelings related to sex or orgasm and behaviors such as masturbation) (Heiman, 2002a). In turn, changes in these factors lead, through feedback loops, to changes in neurological and other biological factors (which underlie orgasm) as well as social factors (the meaning for both partners of an orgasm and the changes in their interactions). A similar set of feedback loops occurs with CBT for vaginismus (ter Kuile et al., 2007): CBT changes thoughts and feelings about penetration, and the responses of the vaginal muscles, making vaginal intercourse with a partner possible.

Although all the techniques mentioned may alleviate sexual dysfunctions, the definition of “success” is less clear-cut than for treatments of most psychological disorders. As we noted at the beginning of this chapter, sexuality and sexual dysfunctions typically involve other people besides the patient, and a treatment that the patient views as successful may not be perceived that way by the partner. Let’s go back to the older gentleman whose erectile dysfunction was treated with Viagra. He may have been pleased by his response to the drug treatment (Althof et al., 2006), only to discover that his wife was now unhappy about his sustained erections and more frequent desire for intercourse. She, then, might be diagnosed with a sexual

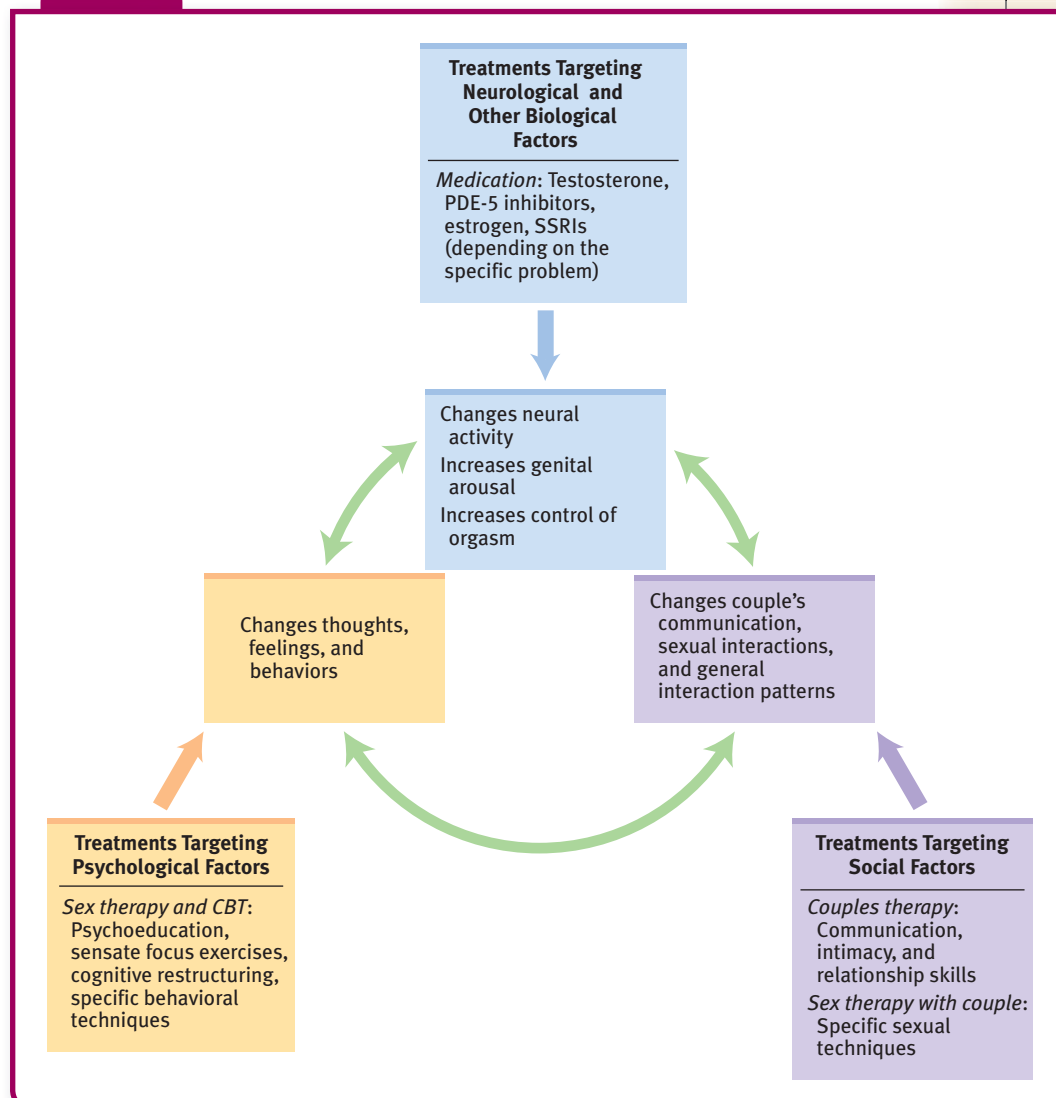

Figure 11.5

11.5 ► Feedback Loops in Treatment: Sexual Dysfunctions

desire problem. Yet she might explain that when her husband had difficulty with his erections, he was much more affectionate, sexually attentive to her, and creative in their sexual interactions. Now he is goal-directed, focusing almost exclusively on intercourse. Solving his erectile dysfunction led to changes in the couple's sexual relations that were not viewed as positive by his wife. Treatments that directly target only one type of factor, such as medication, may seem to resolve the problem for the patient, but instead can—via feedback loops among the three types of factors—have unexpected negative consequences for the couple.

Targeting only a neurological (or other biological) factor in one partner may not improve the overall sexual functioning and satisfaction of the couple.

Key Concepts and Facts About Sexual Dysfunctions

- Sexual dysfunctions are psychological disorders marked by problems in the human sexual response cycle. The response cycle traditionally has been regarded as having four parts: excitement, plateau, orgasm, and resolution—but it is now commonly regarded as beginning with sexual attraction and desire.
- Sexual dysfunctions fall into one of four categories: disorders of desire, arousal, orgasm, and pain. The dysfunctions may be situational or generalized and may arise from neurological (and other biological) factors, psychological factors, or a combination of factors. However, to be classified as dysfunctions they must cause significant distress or problems in the person's relationships.
- Sexual desire disorders involve three components: cognitive, emotional, and, to a lesser extent, neurological (and other biological). Problems with any of these components can lead to hypoactive sexual desire or sexual aversion disorder. Both of these disorders may be diagnosed in men or women.
- Sexual arousal disorders arise when the normal progression through the excitement phase is disrupted. Arousal disorders involve neurological (or other biological), cognitive, and emotional components, although DSM-IV-TR focuses solely on the neurological (or other biological) component. The two disorders pertaining to arousal are female sexual arousal disorder and male erectile disorder.
- Sexual orgasmic disorders are characterized by persistent problems with the orgasmic response after experiencing a normal excitement phase and adequate stimulation. These disorders may involve neurological (and other biological), cognitive, and emotional components. DSM-IV-TR includes three disorders in this category. Two of these involve an absence or delay of orgasmic response: female orgasmic disorder and male orgasmic disorder. Typically, men with orgasmic disorder are able to climax with masturbation but not with vaginal intercourse. The third disorder, premature ejaculation, involves orgasm that occurs persistently with minimal sexual stimulation and before the man wishes it.
- Sexual pain disorders hinge on pain with sexual intercourse. There are two disorders: dyspareunia, which can occur in both men and women, and vaginismus, which occurs only in women.
- Criticisms of the DSM-IV-TR sexual dysfunction disorders include the following: (1) The sexual response cycle may not apply equally well to women; (2) the criteria focus almost exclusively on the neurological (and other biological) components; (3) the end goal is orgasm, not satisfaction; (4) the criteria rest on a particular definition of normal sexual functioning that doesn't encompass normal aging; (5) there are no duration criteria; (6) the definition of distress or interpersonal difficulty caused by the sexual dysfunction is vague; (7) the DSM-IV-TR definitions of the sexual dysfunctions for women aren't necessarily the ones used by specialists in human sexuality; (8) dyspareunia should be considered a pain disorder, not a sexual disorder.

- Various factors contribute to sexual dysfunctions. Neurological (and other biological) factors include disease, illness, surgery or medications, and the normal aging process.
- Psychological factors can be divided into three types: predisposing factors, such as negative attitudes toward sex, negative conditioning experiences, and a history of sexual abuse; precipitating factors, such as anxiety about sex and distraction because of sexual or nonsexual matters; and maintaining factors, such as worrying about future sexual problems.
- Social factors include: the quality of the partners' relationship (how stress, conflict, and communication are handled, and how attracted the partners are to one another); the partner's sexual functioning; a history of abuse; and sexual mores in the individual's subculture (e.g., religious teachings).
- Neurological (and other biological) factors that may contribute to sexual dysfunctions are assessed through tests of endocrine and hormone levels and of the functioning of sensory nerves, internal organs, and the genitals. Psychological factors are sometimes assessed through personality tests and inventories; a clinician will also consider possible comorbid disorders and assess a patient's thoughts and feelings about sexual activities. Social factors include the ways that sexual problems interact with any relationship problems a couple may have.
- Treatments that target neurological (and other biological) are medications for erectile dysfunction and for analogous arousal problems in women.
- Treatments that target psychological factors include psychoeducation, sensate focus exercises, and CBT to counter negative thoughts, beliefs, and behaviors associated with sexual dysfunction. For certain sexual dysfunctions, specific techniques may be particularly helpful.
- Treatments that target social factors address problematic issues in a couple's relationship as well as teach the couple specific sex-related cognitive or behavioral strategies.
- Treatments that focus on one type of factor for a given patient can create complex feedback loops, which sometimes have unexpected—and perhaps negative—consequences for the couple. Successful treatment for a patient might create problems for the partner.

Making a Diagnosis

- Reread Case 11.7 about Sarah and Benjamin, and determine whether either of them meet the criteria for any sexual dysfunction(s). Specifically, examine the criteria for each disorder and determine whether Sarah or Benjamin's symptoms meet each of the criteria for each disorder appropriate to their

sex. If you would like more information to determine their diagnoses, what information—specifically—would you want, and in what ways would the information influence your decision?

- Reread Case 11.8 about Crystal, and determine whether her symptoms meet the criteria for hypoactive sexual desire disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.9 about the stockbroker, and determine whether his symptoms meet the criteria for sexual aversion disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.10 about Harry, and determine whether his symptoms meet the criteria for hypoactive sexual desire disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.11 about Lola, and determine whether her symptoms meet the criteria for female orgasmic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.12 about the man who didn't generally reach orgasm during vaginal intercourse, and determine whether his symptoms meet the criteria for male orgasmic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.13 about Mr. Albert, and determine whether his symptoms meet the criteria for premature ejaculation. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 11.14 about Lynn, and determine whether her symptoms meet the criteria for vaginismus and/or dyspareunia. Specifically, list which criteria of each disorder apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

SUMMING UP

Summary of Gender Identity Disorder

Gender identity disorder is characterized by a persistent cross-gender identification that leads to chronic discomfort with one's biological sex. Symptoms of gender identity disorder often emerge in childhood, but most children diagnosed with the disorder no longer have the disorder by the time they are adults. However, most adults with gender identity disorder report that their symptoms began in childhood.

In children, symptoms of gender identity disorder include cross-dressing, engaging in other-sex types of play, choosing other-sex playmates, and even claiming to be the other sex. In adults, symptoms include persistent and extreme discomfort from living publicly as their biological sex, which leads many to live (at least some of the time) as someone of the other sex.

Criticisms of the diagnostic criteria in DSM-IV-TR for this disorder point to the overly narrow concept of gender and appropriate behavior (particularly for males) and the ambiguous requirement about distress. With gender identity disorder, the person's distress often arises because of other people's reactions to the cross-gender behavior.

Some brain areas in adults with gender identity disorder are more similar to the corresponding brain areas of members of their desired sex than to those of their biological sex. Results from animal studies suggest that one explanation for this disorder is that prenatal exposure to hormones causes the brain to develop in ways more similar to the other sex, although the sexual characteristics of the body are unchanged. Beyond symptoms that are part of the diagnostic criteria for the disorder, no psychological or social factors are clearly associated with the disorder.

Treatments may target neurological (and other biological), psychological, or social factors. Treatments that target neurological and other biological factors include hormone treatments and sex reassignment surgery. Treatments targeting psychological factors include psychoeducation and helping the patient choose among gender-related lifestyle options and problem solve about potential difficulties. Treatments that target social factors include family education, support groups, and group therapy.

Thinking like a clinician

When Nico was a boy, he hated playing with the other boys; he detested sports and loved playing with the girls—playing “house” and “dress

up”—except when the girls made him dress up as “the man” of the group. Sometimes he got to be the princess, and that thrilled him. As a teenager, Nico's closest friends continued to be females. Although Nico shied away from playing with boys, he felt himself sexually attracted to them. To determine whether Nico had gender identity disorder, transvestic fetishism, or no gender or sexual disorder, what information would a clinician want? What specific information would count heavily? Should that fact that Nico is attracted to males affect the assessment? Why or why not?

Summary of The Paraphilias

Paraphilias are characterized by a predictable sexual arousal pattern regarding “deviant” fantasies, objects, or behaviors. Paraphilias can involve (1) nonconsenting partners or children (exhibitionism, voyeurism, frotteurism, and pedophilia), (2) suffering or humiliating oneself or one's partner (sexual masochism and sexual sadism), or (3) arousal by nonhuman objects (fetishism and transvestic fetishism). To be diagnosed with a paraphilia, either the person must have acted on these sexual urges and fantasies, or these arousal patterns must cause the patient significant distress.

Assessments of paraphilias may involve the use of a penile plethysmograph to determine the sorts of stimuli that arouse a man, as well as self-reports of arousing stimuli and reports from partners and from the criminal justice system for those apprehended for sexual crimes.

Criticisms of the DSM-IV-TR paraphilia classification include the following: What is determined to be sexually “deviant” varies across cultures and over time; the diagnostic criteria are overly broad and thereby lead clinicians to group together very different disorders; and the criteria do not address the ability to control the paraphilic urges.

Research shows that paraphilias share similarities with OCD. Additional possible contributing factors include classically conditioned arousal and the Zeigarnik effect.

Most frequently, men who receive treatment for paraphilias because they were ordered to do so by the criminal justice system. Treatments that target neurological factors decrease paraphilic behaviors through medication; however, although the behaviors may decrease, the interests often do not. Treatments that target psychological factors are designed to change cognitive distortions about the predatory sexual behaviors, especially the

false belief that the behavior is not harmful to the nonconsenting victims. A goal of such treatments is to change sexual arousal patterns using behavioral methods, as well as to prevent relapse. Although social factors may be the target of treatment for sex offenders, they have not generally been successful.

Thinking like a clinician

Ben was getting distracted at work because he kept fantasizing about having sexual relations with young boys. He'd think about a neighbor's son or a boy in an advertisement. He hadn't *done* anything about his fantasies, but they were getting increasingly harder to turn off. According to DSM-IV-TR, what paraphilic disorder, if any, does Ben have? On what is your decision based? If Ben wasn't getting distracted by his fantasies, would your diagnosis change or stay the same, and why? Do you think that illegal acts (such as child sex abuse or sexual acts with nonconsenting individuals) should be part of the DSM criteria, as they presently are? Explain your answer. What treatment options are available to Ben?

Summary of Sexual Dysfunctions

Sexual dysfunctions are psychological disorders marked by problems in the human sexual response cycle. The response cycle traditionally has been regarded as having four parts: excitement, plateau, orgasm, and resolution—but it is now commonly regarded as beginning with sexual attraction and desire. Sexual dysfunctions fall into one of four categories: disorders of desire, arousal, orgasm, and pain. The dysfunctions may be situational or generalized and may arise from neurological (and other biological) factors, psychological factors, or a combination of factors. However, to be classified as dysfunctions they must cause significant distress or problems in the person's relationships.

Each sexual dysfunction involves cognitive, emotional, and neurological (and other biological) components to varying degrees; the DSM-IV-TR diagnostic criteria, however, generally focus on neurological and other biological components.

Various factors contribute to sexual dysfunctions. Neurological (and other biological) factors include disease, illness, surgery or medications, and the normal aging process. Psychological factors are divided into predisposing, precipitating, and maintaining factors. Social factors include the quality of the partners' relationship, the partner's

sexual functioning, a history of abuse, and sexual mores in the individual's subculture. All the factors interact via feedback loops. An assessment of sexual dysfunctions may evaluate neurological (and other biological), psychological, and social factors.

Treatments that target neurological (and other biological) factors are medications for erectile dysfunction and for analogous arousal problems in women. Treatments that target psychological factors include psychoeducation and sensate focus exercises, and CBT to counter negative thoughts, beliefs, and behaviors associated with sexual dysfunction. Treatments that target social factors address problematic issues in a couple's relationship as well as teach the couple specific sex-related cognitive or behavioral strategies. Treatments that focus on one type of factor for a given patient can create complex feedback loops, which sometimes have unexpected—and perhaps negative—consequences for the couple.

Thinking like a clinician

Chi-Ling and Yinong were in their 30s and had been trying to have a baby for a year. Their sexual relations were strained: They had sex when the ovulation predictor test kit indicated that they should, and each month's attempt

and subsequent failure made them anxious. There was no joy or love in their sexual relations, and most of the time Chi-Ling was barely aroused and lubricated; she rarely had orgasms anymore. She just wanted Yinong to hurry up and ejaculate, and he was finding it increasingly difficult to do so. Based on what you have read, do you think that Chi-Ling or Yinong has any sexual dysfunctions, and if so, which one(s)? Support your position. If you could obtain additional information before you decide, what would you want to know and why?

Schizophrenia and Other Psychotic Disorders

In 1930, female quadruplets were born in a small Midwestern city. All four survived, which at that time was remarkable. This set of quadruplets (or quads) was also remarkable in two other ways: All four developed from a single fertilized egg and so basically were genetically identical. In addition, all four went on to develop symptoms of schizophrenia as young adults. In the psychological literature, the quadruplets came to be known by pseudonyms they were given to protect their privacy: Nora, Iris, Myra, and Hester Genain.

The quads were born to parents of limited financial means. Their father, Henry, was abusive, violent, and alcoholic. He also exhibited some symptoms of schizophrenia. Their mother, Maud, had been a nurse. Maud was very strict with the girls, but she was a better parent than Henry.

By the time the quads were in their early 20s, three had been hospitalized for schizophrenia at least once, and the fourth was exhibiting symptoms of schizophrenia. Also around that time, Mrs. Genain was recovering from bladder surgery, and it was becoming increasingly difficult for her to care for the young women. The family's problems were brought to the attention of researchers at the National Institute of Mental Health (NIMH), and the family was invited to move to a research and treatment facility in Washington, DC. At the facility, the sisters were treated, studied, and written about extensively. In fact, the pseudonyms the quads were given related to the initials of NIMH: Nora, Iris, Myra, and Hester. Their false last name, Genain, means "dire birth" in Greek.

The fact that all four of the Genain sisters developed symptoms of schizophrenia was by no means an inevitable result. For identical twins, the chance of both twins's developing schizophrenia is about 48%. For identical quads, the odds of all four developing schizophrenia are about one in six, or 16% (Rosenthal, 1963). The quads' story offers possible clues about why all four of them developed schizophrenia and provides some understanding of what causes the disorder. In this chapter, we discuss the symptoms of schizophrenia, what is known about its causes, and current treatments for this disorder.

Chapter Outline

What are Schizophrenia and Other Psychotic Disorders?

Nora, Iris, Myra, and Hester Genain were identical quadruplets. All four suffered from schizophrenia, although this outcome is statistically unlikely. The symptoms and course of the disorder were different for each sister, illustrating the range of ways it can affect people.

What Are Schizophrenia and Other Psychotic Disorders?

Schizophrenia is a psychological disorder characterized by psychotic symptoms—hallucinations and delusions—that significantly affect emotions, behavior, and most notably, mental processes and mental contents. The symptoms of schizophrenia can interfere with a person's abilities to comprehend and respond to the world in a normal way. DSM-IV-TR lists schizophrenia as a single disorder (see Chapter 3, and Table 12.1), but research suggests that schizophrenia is not a unitary disorder (Blanchard, Horan, & Collins, 2005; Turetsky et al., 2002). Instead, like depression (see Chapter 6), schizophrenia is a set of related disorders. Research findings suggest that each variant of schizophrenia has different symptoms, causes, course of development, and, possibly, response to treatments. Let's examine in more detail the symptoms and types of schizophrenia and other related psychotic disorders.

The Symptoms of Schizophrenia

The criteria for schizophrenia in DSM-IV-TR fall into two clusters:

- *positive symptoms*, consisting of delusions and hallucinations and disorganized speech and behavior;
- *negative symptoms*, consisting of the absence or reduction of normal mental processes, mental contents, feelings, or behaviors, including speech, emotional expressiveness, and/or movement.

Let's examine in detail the DSM-IV-TR criteria (Table 12.1), criticisms of these criteria, and an alternative way to diagnose schizophrenia.

Positive Symptoms

Positive symptoms are so named because they are marked by the *presence* of abnormal or distorted mental processes, mental contents, or behaviors. Positive symptoms of schizophrenia are

- hallucinations (distortions of perception),
- delusions (distortions of thought),
- disorganized speech, and
- disorganized behavior.

Schizophrenia

A psychological disorder characterized by psychotic symptoms that significantly affect emotions, behavior, and mental processes and mental contents.

Positive symptoms

Symptoms of schizophrenia that are marked by the *presence* of abnormal or distorted mental processes, mental contents, or behaviors.

Table 12.1 ▶ DSM-IV-TR Diagnostic Criteria for Schizophrenia

A. Characteristic symptoms: Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):

- (1) delusions
- (2) hallucinations
- (3) disorganized speech
- (4) grossly disorganized or catatonic behavior
- (5) negative symptoms, i.e., affective flattening, alogia, or avolition

Note: Only one Criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts or two or more voices conversing with each other.

B. Social/occupational dysfunction: For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning, such as work, interpersonal relations, or self-care, are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

C. Duration: Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

Although DSM-IV-TR divides symptoms of schizophrenia into two categories (positive and negative), current research suggests that the symptoms fall into three clusters, or dimensions: positive, in green (A1 and A2), disorganized, in orange (A3 and A4), and negative, in blue (A5).

These symptoms are distinguished by their extreme quality. From time to time, we all have hallucinations, such as thinking we hear the doorbell ring when it didn't. But the hallucinations experienced by people with schizophrenia are intrusive—they may be voices that talk constantly or scream at the patient. Similarly, a delusion of someone with schizophrenia isn't an isolated, one-time false belief (e.g., "My roommate took my sweater and that's why it's missing"). With schizophrenia and other psychotic disorders, the delusions are extensive, although they often focus on one topic (e.g., "My roommate is out to get me, and the fact that she has taken my sweater is just one more example").

The positive symptoms of disorganized speech and disorganized behavior are apparent from watching or talking to an individual who has them—it's difficult, if not impossible, to understand what's being said, and the individual's behavior is clearly odd (wearing a coat during a heat wave, for example). Let's examine the four positive symptoms in more detail.

Hallucinations

As discussed in Chapter 1, **hallucinations** are sensations so vivid that the perceived objects or events seem real even though they are not. Any of the five senses can be involved in a hallucination, although auditory hallucinations—specifically, hearing voices—are the most common type experienced by people with schizophrenia. Pamela Spiro Wagner describes one of her experiences with auditory hallucinations:

[The voices] have returned with a vengeance, bringing hell to my nights and days. With scathing criticism and a constant scornful commentary on everything I do, they sometimes order me to do things I shouldn't. So far, I've stopped myself, but I might not always be able to. . . .

(Wagner & Spiro, 2005, p. 2)

Research that investigates possible underlying causes of auditory hallucinations finds that people with schizophrenia, and to a lesser extent their unaffected siblings, have difficulty distinguishing between verbal information that is internally generated

Hallucinations

Sensations that are so vivid that the perceived objects or events seem real, even though they are not.

(as when imagining a conversation or talking to oneself) and verbal information that is externally generated (as when another person is actually talking) (Brunelin et al., 2007). People with schizophrenia are also more likely to (mis)attribute their own internal conversations to another person (Brunelin, Combris, et al., 2006; Keefe et al., 1999); this misattribution apparently contributes to the experience of auditory hallucinations.

Delusions

People with schizophrenia may also experience **delusions**—incorrect beliefs that persist, despite evidence to the contrary. Delusions often focus on a particular theme, and several types of themes are common among these patients. For one, *paranoid delusions* involve the theme of being persecuted by others. Pamela Spiro Wagner's paranoid delusions involved extraterrestrials:

I barricade the door each night for fear of beings from the higher dimensions coming to spirit me away, useless as any physical barrier would be against them. I don't mention the NSA, DIA, or Interpol surveillance I've detected in my walls or how intercepted conversations among these agencies have intruded into TV shows.

(Wagner & Spiro, 2005, p. 2)

In contrast, *delusions of control* revolve around the belief that the person is being controlled by other people (or aliens), who literally put thoughts into his or her head, called *thought insertion*:

I came to believe that a local pharmacist was tormenting me by inserting his thoughts into my head, stealing mine, and inducing me to buy things I had no use for. The only way I could escape the influence of his deadly radiation was to walk a circuit a mile in diameter around his drugstore, and then I felt terrified and in terrible danger.

(Wagner, 1996, p. 400)

In this example, note that Wagner believed that it is possible for the pharmacist to insert his thoughts into her head and thus control her.

Another delusional theme is believing oneself to be significantly more powerful, knowledgeable, or capable than is actually the case, referred to as *delusions of grandeur*. Someone with this type of delusion may believe that he or she has invented a new type of computer when such an achievement by that person is clearly impossible. Delusions of grandeur may also include the mistaken belief that the individual is a different—often famous and powerful—person, such as the president or a prominent religious figure.

Yet another delusional theme is present in *delusions of reference*: the belief that external events have special meaning for the individual. Someone who believes that a song playing in a movie is in some kind of code that has special meaning *just for* him or her, for instance, is having a delusion of reference.

Whatever the theme of the delusion, according to DSM-IV-TR, if it is bizarre or clearly implausible, then additional symptoms are not needed for a diagnosis of schizophrenia. An example would be a patient's belief that his or her organs have been replaced, despite the absence of a surgical scar.

Disorganized Speech

People with schizophrenia can sometimes speak incoherently, although they may not necessarily be aware that other people cannot understand what they are saying. Speech can be disorganized in a variety of different ways. One type of disorganized speech is **word salad**, which is a random stream of seemingly unconnected

Drawing by Craig Geiser from Living with Schizophrenia by Stuart Emmons, Craig Geiser, Kalman J. Kaplan, Martin Harrow, Taylor & Francis, 1997.

The man who made this drawing said, "This belt buckle symbolized safety for me in my stay in the hospital. I felt no harm would come to me while I wore it. I also left it visible to me on my nightstand next to my bed at night. I thought several times the belt buckle saved me from whatever was going on. My belt buckle seemed as though it was wearing thinner, using up its strength a little at a time in helping me" (Emmons et al., 1997, p. 183). Although many people have a good luck charm, the fact that this man believed that his belt buckle was getting thinner because it was "using up its strength" suggests that he had a delusional belief about it.

Delusions

Persistent false beliefs that are held despite evidence that the beliefs are incorrect or exaggerate reality.

Word salad

Disorganized speech consisting of a random stream of seemingly unconnected words.

words. For example, a patient might say something like “Pots dog small is tabled.” Another type of disorganized speech involves many *neologisms*, or words that the patient makes up:

That’s *wish-bell*. Double vision. It’s like walking across a person’s eye and reflecting personality. It works on you, like dying and going to the spiritual world, but landing in the *Vella* world.

(Marengo et al., 1985, p. 423)

In this case, “wish-bell” is the neologism; it doesn’t exist, nor does it have an obvious meaning or function as a metaphor.

Disorganized Behavior

Another positive symptom (and recall that *positive* in this context means “present,” not “good”) of schizophrenia is *disorganized behavior*, behavior that is so unfocused and disconnected from a goal that the person cannot successfully accomplish a basic task, or the behavior is inappropriate in the situation. Disorganized behavior can range from laughing inappropriately in response to a serious matter or masturbating in front of others, to being unable to perform normal daily tasks such as washing oneself, putting together a simple meal, or even selecting appropriate clothes to wear.

Hester Genain had symptoms of schizophrenia that began in childhood, including disorganized behavior: “Hester did a lot of strange things. Once Mrs. Genain bought each girl four pairs of new panties, and Hester put on all four pairs over the dirty one she was wearing” (Rosenthal, 1963, p. 52).

The category of disorganized behavior also includes **catatonia** (also referred to as *catatonic behavior*), which occurs when an individual remains in an odd posture or position, with rigid muscles, for hours. For example, during her early 20s, Iris Genain’s symptoms included standing in the same position for hours each evening.

These positive symptoms—hallucinations, delusions, disorganized speech, and disorganized behavior—constitute four of the five DSM-IV-TR symptom criteria for schizophrenia; the fifth criterion is any negative symptom (discussed in the following section). DSM-IV-TR requires that a person have a total of two—out of the five—of these symptoms (see Table 12.1) to be diagnosed with schizophrenia. In order to receive such a diagnosis, then, an individual must have a least one positive symptom.

Negative Symptoms

In contrast to positive symptoms, **negative symptoms** are marked by the *absence* or reduction of normal mental processes, mental contents, or behaviors. DSM-IV-TR specifies three types of negative symptoms: *flat affect*, *alogia*, and *avolition*. Each of these reflects the lack of a normal mental process, expression of feeling, or behavior, but they differ in what—specifically—is lacking. Let’s look more closely at these negative symptoms.

Flat Affect: Muted Expression

Some people with schizophrenia exhibit **flat affect**, which occurs when a person does not display a great range of emotion and hence often seems emotionally neutral. Such people may not express or convey much information through their facial expressions or body language, and they tend to refrain from making eye contact (although they may smile somewhat and do not necessarily come off as “cold”).

Although people with schizophrenia may not display much emotion, that doesn’t necessarily mean that they don’t *experience* much emotion. Studies suggest that their experience of emotion is much like that of other people (Aghevli, Blanchard, & Horan, 2003; Chattopadhyay, 2005; Myin-Germeys, Delespaul, & deVries, 2000). However, this is not apparent from casual observation.

Catatonia

A condition in which an individual remains in an odd posture or position, with rigid muscles, for hours.

Negative symptoms

Symptoms of schizophrenia that are marked by the *absence* or reduction of normal mental processes, mental contents, or behaviors.

Flat affect

A lack of, or considerably diminished, emotional expression, such as occurs when someone speaks robotically and shows little facial expression.

People with schizophrenia may exhibit flat affect—an extremely limited range of emotional expression—which can make them appear emotionally unresponsive. However, these people report experiencing emotions to the same degree as others do.

Alogia

A negative symptom of schizophrenia marked by speaking less than most other people and responding slowly or minimally to questions.

Avolition

A negative symptom of schizophrenia marked by difficulty in initiating or following through with activities.

Executive functions

Mental processes involved in planning, organizing, problem solving, abstract thinking, and exercising good judgment.

Alogia: Poverty of Speech

People with schizophrenia who have **alogia**, or poverty of speech, may respond slowly or minimally to questions and generally speak less than do most other people. A person with alogia will take a while to muster the mental effort necessary to respond to a question. Even choosing among words can be challenging. For example, if asked how he or she liked a television show that just ended, a person with alogia might nod once very briefly. If pushed to explain why the show was enjoyable, he or she might take 5–10 seconds to think and then just say “Funny.”

Avolition: Difficulty Initiating or Following Through

In movies portraying people with schizophrenia, hospitalized patients are often shown sitting in chairs apparently doing nothing all day, not even talking to others. This portrayal suggests **avolition**, the term for difficulty in initiating or following through with activities. For example, Hester Genain would often sit for hours, seemingly staring into space, and had difficulty beginning her chores.

The sets of positive and negative symptoms in DSM-IV-TR grew out of decades of clinical observations of patients with schizophrenia; these symptoms can generally be observed or can be inferred by a trained individual. However, research has revealed that cognitive deficits—which are not part of the DSM-IV-TR criteria—also play a crucial role in schizophrenia. Let’s examine these deficits.

Cognitive Deficits: The Specifics

Research has revealed the important role that cognitive deficits (also called *neurocognitive deficits*) play in the course and prognosis of schizophrenia (Barch, 2005; Green, 2001). In this section, we examine specific deficits in attention, memory, and executive functioning that arise in most people with schizophrenia (Keefe, Eesley, & Poe, 2005; Wilk et al., 2005).

Deficits in Attention

Cognitive deficits include difficulties in sustaining and focusing attention, which can involve distinguishing relevant from irrelevant stimuli (Gur et al., 2007). One individual with schizophrenia recounted: “If I am talking to someone they only need to cross their legs or scratch their heads and I am distracted and forget what I was saying” (Torrey, 2001, p. 29).

Deficits in Working Memory

Another area of cognitive functioning adversely affected in people with schizophrenia is *working memory*, which consists of short-term memory and a set of executive processes that operate on information in short-term memory (for example, by ordering it in new ways). Working memory organizes and transforms incoming information so that it will be available to be remembered later and also is involved in reasoning and related mental activities (Baddeley, 1986). For example, if you are trying to remember items you need to buy at the store, you will probably use working memory to organize the items into easy-to-recall categories. People with schizophrenia do not organize information effectively, which indicates that their working memories are impaired; they may not remember something they were told or shown once or even a few times.

However, when presented with information on multiple occasions, people with schizophrenia are able to store the information in long-term memory. Once the information is successfully stored, they will remember it as well as people who do not have schizophrenia (Chan et al., 2000; Green, 2001). Deficits in working memory may also lead to disruptions in reasoning—and hence to disorganized speech (Melinder & Barch, 2003).

Deficits in Executive Functioning

The problems with working memory apparently arise because people with schizophrenia often have difficulty with **executive functions**, which are mental processes involved in planning, organizing, problem solving, abstract thinking, and exercising good judgment (Cornblatt et al., 1997; Erlenmeyer-Kimling et al., 2000; Kim et al.,

2004). Executive functions are required to organize, interpret, and transform information in working memory—and hence a problem with such functioning will disrupt working memory. But more than this, the problems with executive functioning have far-reaching consequences for cognition in general. For instance, Hester had the most severe symptoms of the Genain quads, and her deficits in executive functioning were prominent much of the time. She had difficulty performing household chores that required multiple steps—such as making mashed potatoes by herself, which required peeling the potatoes, then boiling them, knowing when to take them out of the water, and mashing them with other (measured) ingredients. When Hester was not actively psychotic, she would be able to perform the first step of a multistep task, but only after she had finished that step could she begin to plan and implement a second step. After she completed each step, she needed to receive instructions for the next one. Obviously, deficits in executive functioning can impair a person's overall ability to function.

Cognitive Deficits Endure Over Time

Neurocognitive deficits do not necessarily make their first appearance at the same time that the DSM-IV-TR symptoms of schizophrenia first emerge. For many people who develop schizophrenia, cognitive deficits exist in childhood, well before a first episode of schizophrenia (Cannon et al., 1999; Erlenmeyer-Kimling et al., 2000; Fish et al., 1992; Fuller et al., 2002; Ott et al., 2002; Torrey, 2002). In addition to predating symptoms of schizophrenia, cognitive deficits often persist after the DSM-IV-TR symptoms improve (Hoff & Kremen, 2003; Hughes et al., 2003; Rund et al., 2004; Tsuang, Stone, & Faraone, 2000).

The lives of Genain sisters illustrate both the importance of cognitive deficits and their variety. Hester had the most difficulty academically and was held back in 5th grade because of her inadequate school performance. Moreover, she had difficulty carrying out simple household tasks and seemed to suffer from deficits in attention, memory, and executive functioning. The cognitive functioning of the other quads did not appear to be as impaired. In fact, Myra did not exhibit any significant cognitive deficits, and she graduated from high school, held a job, married, and had two children. Nora and Iris had moderate levels of cognitive deficits; they could perform full-time work for periods of time but could not function independently for long stretches (Mirsky & Quinn, 1988; Mirsky et al., 1987, 2000).

Limitations of DSM-IV-TR Criteria

Although the DSM-IV-TR criteria provide a relatively reliable way to diagnose schizophrenia, a number of researchers point to drawbacks of those criteria—both of the specific criteria and of the grouping of positive and negative symptoms (Fauman, 2006; Green, 2001). A more diagnostically and prognostically relevant set of symptoms, these researchers suggest, would focus on the extent of cognitive deficits and the breadth and severity of the DSM-IV-TR symptoms.

Absence of Focus on Cognitive and Social Functioning

Cognitive deficits are not specifically addressed by the DSM-IV-TR criteria, despite their importance. Specifically, although the DSM-IV-TR set of positive symptoms includes disorganized speech and disorganized behavior (see Table 12.1), research suggests that these two symptoms together form an important cluster, independent of hallucinations and delusions. Moreover, these symptoms arise from underlying cognitive deficits that contribute to disorganized thinking. For instance, cognitive deficits can cause thoughts to skip from one topic to another, topics that are related to each other only tangentially if at all (this problem is referred to as a *loosening of associations*). Thus, disorganized speech arises from disorganized thinking, but such thinking is not part of the DSM-IV-TR criteria. Similarly, disorganized behavior, such as laughing at a funeral or putting on four pairs of underwear, can arise because the individual's cognitive deficits prevent him or her from organizing social experiences into categories covered by general rules of behavior or conventions.

Cognitive deficits can also lead to unusual, although not necessarily disorganized, social behavior. As we'll discuss in more detail later, people with schizophrenia may be socially isolated and avoid contact with others because such interactions can be overwhelming or confusing. People with schizophrenia can have difficulty understanding the usual, unspoken rules of social convention. Also, even after an episode of schizophrenia has abated, they may not understand when someone is irritated because they do not notice or correctly interpret the other person's facial expression or tone of voice. When irritation erupts into anger, it can seem to come out of the blue, frightening and overwhelming people with schizophrenia. So, they may try to tread a safer path and avoid others as much as possible.

The poor social skills and social isolation that are frequently a part of schizophrenia are not included in the DSM-IV-TR criteria, although they are related to an impaired ability to work (Dickinson, Bellack, & Gold, 2007). The disorganized behavior, social isolation and poor social skills, and perhaps avolition, all are indicators of underlying cognitive deficits (Farrow et al., 2005).

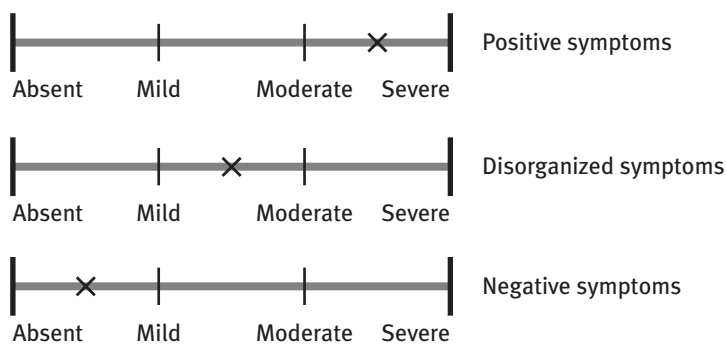

Categorical, Not Continual

The DSM-IV-TR definition of schizophrenia (and other disorders; see Chapter 3) is categorical—that is, someone's symptoms either meet the criteria (in this case, indicate that he or she has schizophrenia) or do not. Some researchers in the field question whether schizophrenia is best described as a category and suggest that instead it should be regarded

as located on a continuum (Tsuang, Stone, & Faraone, 2000; Westen et al., 2002). Recognizing this limitation, DSM-IV-TR does provide an alternative way to diagnose schizophrenia, allowing the clinician to rate the symptoms as absent, mild, moderate, or severe (American Psychiatric Association, 2000).

Moreover, the list of symptoms is divided into three dimensions: positive (hallucinations and delusions), disorganized (speech and behavior, and inappropriate affect), and negative (alogia, avolition, or flat affect), and each dimension is rated separately. These dimensions better reflect how the symptoms cluster together: Symptoms within each of these dimensions tend to vary with each other more than they do with symptoms on other dimensions. Thus, someone with severe hallucinations is more likely to have severe delusions as well, but not necessarily to have severe negative symptoms. As shown in Figure 12.1, the alternative system in DSM-IV-TR enables clinicians and researchers to note that someone with schizophrenia has differing levels of symptom severity across each of the three dimensions. In keeping with current research, this chapter discusses disorganized symptoms as a separate symptom cluster.

Figure 12.1

12.1 ► Symptoms of Schizophrenia as Positions on Continuous Dimensions

In DSM-IV-TR's alternative way of diagnosing schizophrenia, symptoms within the three symptom clusters are rated on a continuum from absent to severe. Symptoms within each cluster tend to vary together, but independently of the other clusters. In the example shown, the individual has severe positive symptoms, moderate disorganized symptoms, and only mild negative symptoms.

Subtypes of Schizophrenia

DSM-IV-TR specifies a set of subtypes of schizophrenia, which are based on the presence or absence of particular positive symptoms. Over time, the diagnosis of subtype may change, as the prominence of different symptoms shifts (Reichenberg, Reickmann, & Harvery, 2005). Information on the importance of cognitive deficits in schizophrenia has led many researchers to use an alternative set of subtypes. Let's examine both sets.

DSM-IV-TR Subtypes

DSM-IV-TR identifies five subtypes of schizophrenia: paranoid, disorganized, catatonic, undifferentiated, and residual.

Paranoid Schizophrenia

Paranoid schizophrenia is characterized by the presence of delusions and auditory hallucinations that are limited to specific topics that have a coherent paranoid or

Paranoid schizophrenia

The subtype of schizophrenia characterized by the presence of delusions and auditory hallucinations that are limited to specific topics that have a coherent paranoid or grandiose theme.

grandiose theme. An example of a paranoid theme is that the person believes that he or she is being hunted by the CIA; an example of a grandiose theme is that the person believes that he or she is God. Pamela Spiro Wagner describes one of her paranoid delusions, which involves being hunted by “the Five People”:

The computers at the drugstore across the street, programmed by the Five People, have tapped into my TV set and monitor my activities with special radar. If I go out, special agents keep every one of my movements under surveillance. A man lighting a cigarette near the drugstore uses his lighter to signal to another just down the street, warning him of my approach. Another alerts conspirators inside. Nothing I do, indoors or out, goes unremarked.

(Wagner & Spiro, 2005, p. 205)

People with paranoid schizophrenia can have relatively intact cognitive and emotional functioning when the content of their thoughts and experiences does not relate to their delusion.

Diagnosing people with paranoid schizophrenia can be difficult because they may seem normal if they don’t talk about the topic of their delusions. Although the paranoid subtype has the best recovery rate (Fenton & McGlashan, 1991), it is also the subtype most associated with aggressive behavior. People with this subtype of schizophrenia can act aggressively toward either themselves or others, and they have the highest suicide rate, 13%, among all patients with schizophrenia (Fenton & McGlashan, 1991).

Disorganized Schizophrenia

Disorganized speech and behavior and inappropriate emotional expression are typical of the subtype called **disorganized schizophrenia**. People with disorganized schizophrenia may giggle, dress strangely, speak obscenely or incoherently (like Emilio in Case 12.1), or urinate or defecate in public. People with disorganized schizophrenia generally have a poor prognosis and, because of their inability to care for themselves, may require constant care.

CASE 12.1 ► FROM THE OUTSIDE: Disorganized Schizophrenia

Emilio is a 40-year-old man who looks 10 years younger. He is brought to the hospital, his twelfth hospitalization, by his mother because she is afraid of him. He is dressed in a ragged overcoat, bedroom slippers, and a baseball cap and wears several medals around his neck. His affect ranges from anger at his mother (“She feeds me shit . . . what comes out of other people’s rectums”) to a giggling, obsequious seductiveness toward the interviewer. His speech and manner have a childlike quality, and he walks with a mincing step and exaggerated hip movements. His mother reports that he stopped taking his medication about a month ago and has since begun to hear voices and to look and act more bizarrely. When asked what he has been doing, he says, “eating wires and lighting fires.” His spontaneous speech is often incoherent and marked by frequent rhyming and clang associations (speech in which sounds, rather than meaningful relationships, govern word choice).

Emilio’s first hospitalization occurred after he dropped out of school at age 16, and since that time he has never been able to attend school or hold a job. He has been treated with neuroleptics [antipsychotic medications] during his hospitalizations but doesn’t continue to take medication when he leaves, so he quickly becomes disorganized again. He lives with his elderly mother, but sometimes disappears for several months at a time and is eventually picked up by the police as he wanders in the streets. There is no known history of drug or alcohol abuse.

(Spitzer et al., 2002, pp. 189–190)

Catatonic Schizophrenia

Catatonic schizophrenia is characterized by catatonic (stiff or seemingly “frozen”) postures or poses, bizarre jerky movements, or frozen facial expressions. A person with catatonic schizophrenia also may not speak, may involuntarily and senselessly repeat words or phrases said by others, or may mimic other people’s bodily movements. Because they are unable to take care of themselves, such as by eating and washing, people with catatonic schizophrenia require constant care.

Disorganized schizophrenia

The subtype of schizophrenia characterized by disorganized speech and behavior and inappropriate emotional expression.

Catatonic schizophrenia

The subtype of schizophrenia characterized by stiff or “frozen” postures or poses, bizarre jerky movements, or frozen facial expression.

Grunitus Studio/Photo Researchers

This woman suffers from catatonic schizophrenia. People diagnosed with this subtype of schizophrenia assume odd postures or poses for hours at a time, and may senselessly repeat words or remain mute. People with catatonic schizophrenia typically cannot care for themselves and require constant attention.

Undifferentiated Schizophrenia

When someone's symptoms lead to the diagnosis of schizophrenia but do not completely match those specified for paranoid, disorganized, or catatonic schizophrenia, the individual will be diagnosed with the subtype **undifferentiated schizophrenia**.

Residual Schizophrenia

Regardless of the subtype of schizophrenia that someone has, when the positive (and disorganized) symptoms have subsided but the negative symptoms persist, the full criteria for schizophrenia are no longer met; the person's subtype classification changes to *residual schizophrenia*, which indicates that there is a residue of (negative) symptoms but the pronounced positive symptoms have faded away. Residual schizophrenia may also be diagnosed when prominent negative symptoms are absent but two or more mild positive symptoms, such as odd beliefs that are not delusional, are present (American Psychiatric Association, 2000). The diagnosis of residual schizophrenia may apply only during a brief period, for example, during an individual's transition from a psychotic state to remission. Sometimes, though, an individual's symptoms may be such that the diagnosis of residual schizophrenia is assigned indefinitely.

Deficit/Nondeficit Subtypes

In contrast to the DSM-IV-TR subtypes of schizophrenia, an alternative set of subtypes is based on the presence or absence of neurocognitive deficits (Horan & Blanchard, 2003; Kirkpatrick et al., 1989). The *deficit subtype* requires the presence of severe neurocognitive deficits in attention, memory, and executive functioning, as well as the positive and negative symptoms that are manifestations of these deficits, such as disorganized speech and behavior and alogia. Such patients are generally more impaired than are other patients with schizophrenia, their symptoms are less likely to improve with currently available treatments, and they have a poorer prognosis.

The *nondeficit subtype* requires the presence of primarily positive symptoms, such as hallucinations and delusions, in conjunction with relatively intact cognitive functioning. People with this subtype are generally less impaired, and they have a better prognosis (McGlashan & Fenton, 1993). Someone with the paranoid subtype in DSM-IV-TR is considered to have the nondeficit subtype.

Distinguishing Between Schizophrenia and Other Disorders

Positive or negative symptoms may arise in schizophrenia or in the context of other disorders. Clinicians and researchers must determine whether the positive or negative symptoms reflect schizophrenia, another disorder, or, in some cases, schizophrenia *and* another disorder. Let's examine the other disorders that have symptoms similar to those of schizophrenia and consider how these disorders are distinguished from schizophrenia. We will contrast schizophrenia with mood disorders, substance-related disorders, and a set of various psychotic disorders—including schizophreniform and brief psychotic disorders, schizoaffective disorder, delusional disorder, shared psychotic disorder, and schizotypal personality disorder.

Psychotic Symptoms in Schizophrenia, Mood Disorders, and Substance-Related Disorders

Other psychological disorders, most notably mood disorders and substance-related disorders, may involve symptoms such as hallucinations and delusions. (Mood disorders with psychotic features are discussed in Chapter 6, and substance-induced hallucinations and delusions are discussed in Chapter 9.) The nature of these psychotic symptoms is usually consistent with the characteristics of the mood disorder

Undifferentiated schizophrenia

The subtype of schizophrenia characterized by symptoms that do not completely match those specified for the paranoid, disorganized, or catatonic subtype.

or substance-related disorder, and the psychotic symptoms only arise during a mood episode or with substance use or withdrawal. For instance, people with mania may become psychotic, developing grandiose delusions about their abilities. Psychotic mania is distinguished from schizophrenia by the presence of other symptoms of mania—such as pressured speech or little need for sleep. Psychotically depressed people may have delusions or hallucinations; the delusions usually involve themes of the depressed person’s worthlessness or the “badness” of certain body parts (e.g., “My intestines are rotting”).

Substance-related disorders can lead to delusions (see Chapter 9), such as the paranoid delusions that arise from chronic use of stimulants. Substances (and withdrawal from them) can also induce hallucinations, such as the tactile hallucinations that can arise with cocaine use (e.g., the feeling that bugs are crawling over a person’s arms).

Some negative symptoms of schizophrenia can be difficult to distinguish from symptoms of other disorders, notably depression: People with schizophrenia or depression may show little interest in activities, hardly speak at all, give minimal replies to questions, and avoid social situations (American Psychiatric Association, 2000). As noted in Table 12.2, although both of these disorders may involve similar outward behaviors, the behaviors arise from different causes. With schizophrenia, these behavioral symptoms stem from the cognitive deficits associated with the disorder. In general, people with schizophrenia but not depression do not have other symptoms of depression, such as changes in weight or sleep or feelings of worthlessness and guilt (American Psychiatric Association, 2000). Of course, people with schizophrenia may develop comorbid disorders, such as depression or substance abuse. The presence of any comorbid disorder can make it more difficult to determine the correct diagnoses.

Table 12.2 ► Behavioral Symptoms Common to Depression and Schizophrenia

Behavioral Symptoms	Causes in Depression	Causes in Schizophrenia
Little or no interest in activities, staring into space for long periods of time	Lack of pleasure in activities (anhedonia), difficulty making decisions	Difficulty initiating behavior (avolition)
Short or “empty” replies to questions	Lack of energy	Difficulty organizing thoughts to speak
Social isolation	Lack of energy, anhedonia, feeling undeserving of companionship	Feeling overwhelmed by social situations, lack of social skills

Psychotic Disorders

Although mood disorders and substance-related disorders may involve psychotic symptoms, the diagnostic criteria for these two categories of disorders do not specifically require the presence of psychotic symptoms. In contrast, the criteria for the disorders collectively referred to as *psychotic disorders* specifically require the presence of psychotic symptoms. Psychotic disorders are considered to lie on a spectrum, related to each other in their symptoms and risk factors but differing in their specific constellations of symptoms, duration, and severity. In addition to schizophrenia, these disorders include schizophreniform disorder, brief psychotic disorder, schizoaffective disorder, delusional disorder, and shared psychotic disorder. Although it is not classified as a psychotic disorder, the personality disorder *schizotypal personality disorder* (discussed in Chapter 13) is thought to be part of the spectrum of schizophrenia-related disorders (Kendler, Neale, & Walsh, 1995). Let’s examine each of these disorders in turn.

Schizophreniform disorder

The psychotic disorder characterized by symptoms that meet all the criteria for schizophrenia *except* that the symptoms have been present for only 1–6 months and daily functioning may or may not have declined over that period of time.

Brief psychotic disorder

The psychotic disorder characterized by the sudden onset of positive or disorganized symptoms that last between a day and a month and are followed by a full recovery.

Schizoaffective disorder

The psychotic disorder characterized by the presence of both schizophrenia *and* a depressive, manic, or mixed mood episode.

Delusional disorder

The psychotic disorder characterized by the presence of nonbizarre but demonstrably incorrect beliefs that have persisted for more than 1 month.

Schizophreniform and Brief Psychotic Disorders

In some cases, an individual's symptoms may meet most, but not all, of the criteria for a diagnosis of schizophrenia. The individual clearly suffers from some psychotic symptoms and has significant difficulty in functioning as a result of his or her psychological problems. However, the impaired functioning hasn't been present for the minimum 6-month duration required for a diagnosis of schizophrenia. Two disorders fall into this class, depending on the specifics of the symptoms and their duration.

Schizophreniform disorder is the diagnosis given when a person's symptoms meet all the criteria for schizophrenia *except* that the symptoms have been present for only 1–6 months (American Psychiatric Association, 2000). In addition, daily functioning may or may not have declined over that period of time. If the symptoms persist for more than 6 months (and daily functioning significantly declines, if it hasn't already), the diagnosis shifts to schizophrenia.

In contrast, **brief psychotic disorder** refers to the sudden onset of psychotic symptoms (hallucinations and delusions), symptoms of disorganized speech or behavior, or catatonic behavior, that last between a day and a month and are followed by a full recovery (American Psychiatric Association, 2000). With this disorder, no negative symptoms should be present during the episode. Rather, brief psychotic disorder is marked by intense emotional episodes and confusion, during which the person may be so disorganized that he or she can't function safely and independently; he or she also has a higher risk of suicide during the time of the episode. Once recovered, people who had this disorder have a good prognosis for full recovery (Pillman et al., 2002).

Schizoaffective Disorder

Schizoaffective disorder is characterized by the presence of both schizophrenia *and* a depressive, manic, or mixed mood episode (see Chapter 6). Because schizoaffective disorder involves mood episodes, negative symptoms such as flat affect are not common, and the diagnosis is likely to be made solely on the basis of positive symptoms. Because of their mood episodes, people with schizoaffective disorder are at greater risk for committing suicide than are people with schizophrenia (Bhatia et al., 2006; De Hert, McKenzie, & Peuskens, 2001). The prognosis for recovery from schizoaffective disorder is better than that for recovery from schizophrenia, particularly when stressors or events clearly contribute to the disorder (American Psychiatric Association, 2000).

Delusional Disorder

When a person's sole symptom is that he or she adheres to nonbizarre but demonstrably incorrect beliefs—those that are theoretically plausible, such as believing that someone is following you—and those beliefs have persisted for more than 1 month, that person is diagnosed with **delusional disorder**. Note that the assessment of the bizarreness of the beliefs distinguishes schizophrenia (bizarre) from delusional disorder (nonbizarre). What is interpreted as being bizarre will vary across clinicians, depending on their experience with people from different subcultures, ethnic groups, or countries; what may seem bizarre to a clinician, though, may be understandable given a particular patient's background and experience (Mullen, 2003). Clinicians and researchers have identified the following types of nonbizarre delusions (American Psychiatric Association, 2000):

- **Erotomanic.** The belief that another person is in love with the patient. This delusion usually focuses on romantic or spiritual union rather than sexual attraction. It is common for people with erotomania to try to contact the person who is the object of their delusion.
- **Grandiose.** The belief that the patient has a great (but unrecognized) ability, talent, or achievement.
- **Persecutory.** The belief that the patient is being spied on, drugged, harassed, or otherwise conspired against. Small snubs or slights are magnified in the patient's eyes, and he or she may seek legal action to redress these perceived insults. People with this delusion sometimes become violent against those whom they perceive as harming them.

Jeff Kravitz/FilmMagic/Getty Images

Brian To/FilmMagic/Getty Images

Diana Napolis suffered from persecutory delusions about filmmaker Stephen Spielberg and singer and actress Jennifer Love Hewitt; she believed that both were controlling her brain (Soto, 2003).

- *Somatic*. The false belief that the patient is experiencing bodily sensations (such as insects on the skin) or bodily malfunctions (such as a foul odor coming from a body cavity).
- *Jealous*. The belief that the patient's partner is unfaithful. This belief is based on tiny amounts of "evidence," such as the partner's arriving home a few minutes late. The patient is likely to confront his or her partner with the "evidence" and may try to "prevent" further unfaithful acts by following or attacking the partner.

People with delusional disorder—like those with the paranoid subtype of schizophrenia—may appear normal when they are not talking about their delusions: Their behavior may not be particularly odd nor their functioning otherwise impaired. The prognosis for people with this disorder is mixed. For some, the delusions may ebb and flow, sometimes interfering with daily life and sometimes fading into the background and not having any effect; for others, the delusions may dwindle away and not reappear.

Henry Genain, the quads' father, exhibited some signs of delusional disorder of the jealous type: Soon after he met Maud, the Genains' mother, he asked her to marry him, but she refused. He pestered her for months, threatening that if she didn't marry him, neither of them would live to marry anyone else. On multiple occasions, he threatened to kill himself or her. After she consented to marry him (because his family begged her to), he didn't want her to socialize with anyone else, including her family: "I want you with me. I'm not going to let you go among other people. . . . I wouldn't trust no woman. All women are weak. I'm not going to trust you either" (Rosenthal, 1963, p. 33). His jealousy was so extreme that he didn't want her to go out of the house because people walking down the street might smile at her. When the quads were 7 years old, Mrs. Genain thought of leaving Henry, but he told her, "If you leave me, I will find you where you go and I'll kill you" (Rosenthal, 1963, p. 69). She believed him and stayed with him.

Shared Psychotic Disorder

Have you ever worried about "catching" a psychological disorder? Probably not. However, in rare cases, something very much like this seems to occur. Perhaps the most exotic psychotic disorder is **shared psychotic disorder** (or *folie à deux*, which is French for "paired madness"), which occurs when an individual develops delusions as a result of his or her close relationship with another person who has delusions as

Shared psychotic disorder

The psychotic disorder in which an individual develops delusions as a result of his or her close relationship with another person who has delusions as part of a psychotic disorder; also known as *folie à deux*.

Wanda Barzee and her husband, Brian David Mitchell, kidnapped 14-year-old Elizabeth Smart in 2002. Mitchell believed he was God, and Barzee apparently came to share his belief. Although diagnosing Barzee was difficult, some doctors who examined her believed that she had shared psychotic disorder.

Salt Lake County Sheriff's Department/Getty Images

ing messages to her. She lived with her two older sisters and convinced them that God was talking to her and that they should join her in taking over a nearby house because God wished it. Her sisters came to share the delusions; they attempted to burglarize the house but were arrested. When the older sisters were separated from their ill sister, their delusions abated (Joshi, Frierson, & Gunter, 2006).

Schizotypal Personality Disorder

Eccentric behaviors and difficulty with relationships are the hallmarks of *schizotypal personality disorder*, to be discussed in more detail with the other personality disorders in Chapter 13. Although schizotypal personality disorder is not technically a psychotic disorder, we mention it here because some research suggests that it may in fact be a milder form of schizophrenia (Dickey, McCarley, & Shenton, 2002). With this personality disorder, problems in relationships may become evident in early adulthood, marked by discomfort when relating to others as well as by being stiff or inappropriate in relationships. However, before you start to become concerned for yourself or someone you know, keep in mind that relationship difficulties are not enough for a diagnosis of schizotypal personality disorder; eccentric behavior, such as having unusual mannerisms or difficulty following social conventions, must also be present. For example, people with schizotypal personality disorder may not make eye contact and may look to one side of a person's face when they speak to him or her (and, to complicate things a bit, to be considered a symptom of schizotypal personality disorder, such behavior should not be due to social anxiety disorder). A person with schizotypal personality disorder may have very few if any close friends, may feel that he or she doesn't fit in, and may experience social anxiety. Schizotypal personality disorder, unlike schizophrenia, does not involve psychotic symptoms. Table 12.3 summarizes the features of the psychotic disorders.

Figure 12.2 shows a decision tree for diagnosing psychotic disorders.

Schizophrenia Facts in Detail

In this section we will discuss additional facts about schizophrenia—how common it is, the disorders that are most frequently comorbid with it, gender and cultural factors related to the disorder, and the prognosis for patients with the disorder.

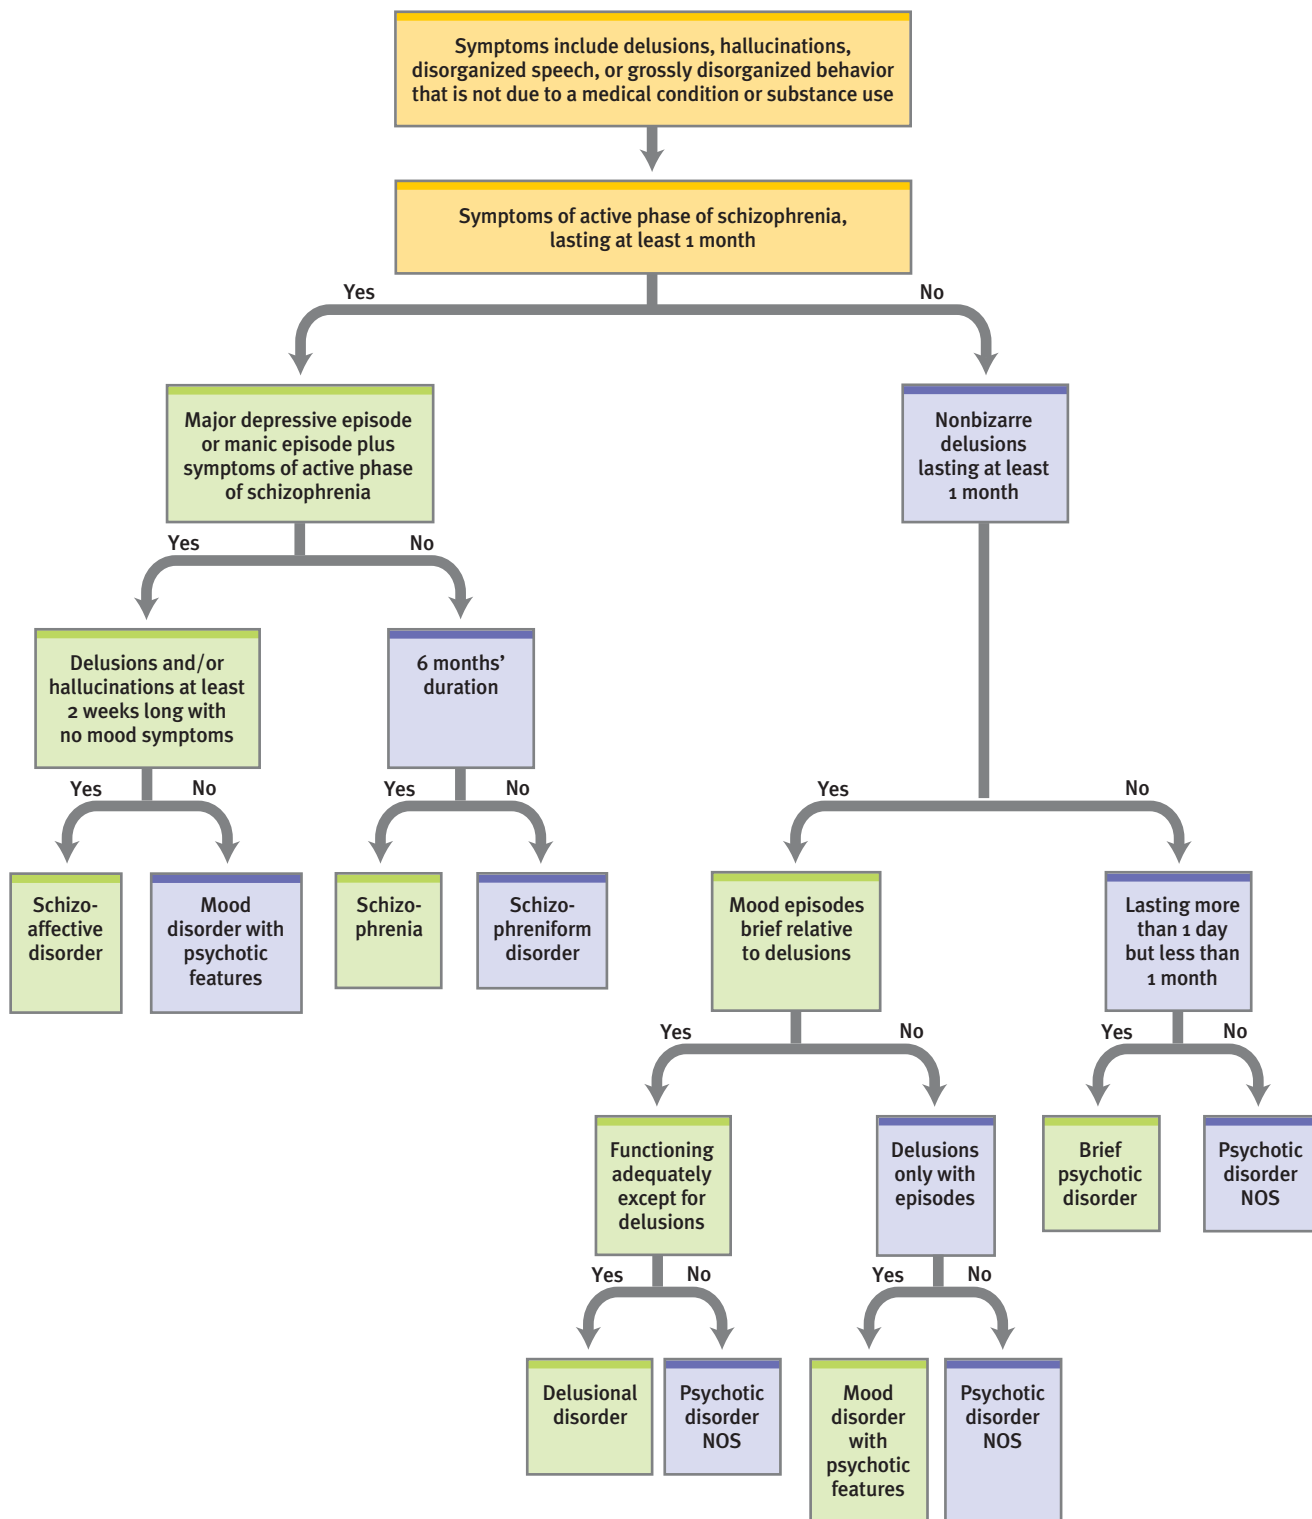

Prevalence

The world over—from China or Finland to the United States or New Guinea—approximately 1% of the population will develop schizophrenia at some point in their lives (Gottesman, 1991; Perälä et al., 2007).

Schizophrenia is one of the top five causes of disability among adults in developed nations, ranking with heart disease, arthritis, drug use, and HIV (Murray & Lopez, 1996). In the United States, about 5% of people with schizophrenia (about

part of a psychotic disorder. The person who had the disorder at the outset is referred to as the primary person and is usually diagnosed with schizophrenia or delusional disorder. The individual diagnosed with shared psychotic disorder comes to adopt the delusions of his or her close friend or family member. The delusions of the primary person may be shared by more than one other person, as can occur in families when the primary person is a parent. When the primary person's delusions subside, the other person's shared delusions may or may not subside as well.

For example, in one case of shared psychotic disorder, the primary person was a young woman with hallucinations and delusions; she was later diagnosed with schizophrenia. She believed that God was send-

Figure 12.2**12.2 ▶ Differential Diagnosis Decision Tree for Psychotic Disorders**

Note: NOS stands for "not otherwise specified." A psychotic disorder NOS is one in which psychotic symptoms significantly cause distress or impair functioning but do not match the full criteria for any other disorder in this category.

Source: Adapted from American Psychiatric Association, 2000, Appendix A, pp. 750–751.

The various psychotic disorders have in common the presence of psychotic symptoms: hallucinations and/or delusions. Although schizotypal personality disorder is not a psychotic disorder (because hallucinations and delusions are absent), this personality disorder is considered to be on the spectrum of schizophrenia-related disorders.

Table 12.3 ▶ Overview of Psychotic Disorders

Psychotic Disorder	Features
Schizophrenia	At least two symptoms, one of which must be positive, for a minimum of 1 month; continuous symptoms for at least 6 months, during which time the individual has impaired functioning in some area(s) of life. <i>Note: Full criteria are listed in Table 12.1.</i>
Schizophreniform Disorder	Symptoms meet all the criteria for schizophrenia <i>except</i> that the symptoms have been present for only 1–6 months; daily functioning may or may not have declined over that period of time.
Brief Psychotic Disorder	The sudden onset of positive symptoms or disorganization, which persists between a day and a month, followed by a full recovery. No negative symptoms are present during the episode.
Schizoaffective Disorder	Symptoms meet the criteria for both schizophrenia and mood disorder. Negative symptoms of schizophrenia are less common with this disorder.
Delusional Disorder	The presence of delusions that are not bizarre but are demonstrably incorrect and that persist for more than 1 month.
Shared Psychotic Disorder (folie à deux)	Delusions that arise as a result of the individual's close relationship with another person who has delusions as part of a psychotic disorder.

Figure 12.3

12.3 ▶ Distribution of the 2.2 Million Americans with Schizophrenia

100,000 individuals) are homeless, 5% are in hospitals, and 6% are in jail or prison (Torrey, 2001). Together, these three groups of people represent about 16% of Americans with schizophrenia; in contrast, 34% of people with this disorder live independently (see Figure 12.3).

Comorbidity

Over 90% of people with schizophrenia also suffer from at least one other psychological disorder (American Psychiatric Association, 2000; Sands & Harrow, 1999). Substance-related disorders, mood disorders, and anxiety disorders are the most common comorbid disorders.

Mood Disorders and Anxiety Disorders

Approximately 80% of people with schizophrenia also have some type of mood disorder, most commonly depression (Alexander, 1996; Sands & Harrow, 1999). As noted earlier, such individuals are said to have a *schizoaffective disorder*. Iris Genain, for instance, suffered from “deep depressions” and might today be diagnosed with schizoaffective disorder. Many people with schizophrenia also have significant anxiety problems: Almost half of them also have

panic attacks (Goodwin, Lyons, & McNally, 2002) and anxiety disorders (Cosoff & Hafner, 1998).

Substance-Related Disorders

Up to 60% of people with schizophrenia have a substance abuse problem that is not related to tobacco (Swartz et al., 2006). Moreover, 90% of those with schizophrenia smoke cigarettes (Regier et al., 1990), and they tend to inhale more deeply than do other smokers (Tidey et al., 2005). One hypothesis for the high comorbidity with

nicotine dependence is that the cigarette use is a form of self-medication, because the nicotine affects certain receptors in the brain related to symptoms of schizophrenia (Kumari & Postma, 2005).

In addition, some people with schizophrenia may use alcohol and other drugs to alleviate their symptoms:

The voices are like people having a conversation inside my head of which I am not a part. They can be like scratching, whispers, or real loud, like shouting. They clutter my mind and I cannot think straight until I am unable to do anything. . . . When I first heard the voices, I would drink until I passed out. When I woke up with a vicious hangover, the voices would be there like thunder, and I would start drinking again.

(Hummingbird, 1999, pp. 863–864)

As is clear from this patient's description, drinking brought temporary relief from intrusive and persistent auditory hallucinations.

Researchers have also noted that even before their positive symptoms emerged, some people with schizophrenia abused drugs, particularly nicotine (cigarettes), marijuana, amphetamines, phencyclidine (PCP), mescaline, and lysergic acid diethylamide (LSD) (Bowers et al., 2001; Weiser et al., 2004). For example, a study of Swedish males found that those who used marijuana in adolescence were more likely later to develop schizophrenia. The more a person used marijuana, the more likely he or she was to develop schizophrenia, particularly if the drug was used more than 50 times (Moore et al., 2007; Zammit et al., 2002). Similarly, a longitudinal study found that girls who used marijuana by age 18 and then later developed schizophrenia had more symptoms of schizophrenia at age 26 than did controls; other studies have found similar results (Arseneault et al., 2002; Verdoux et al., 2003).

Without question, frequent use of marijuana is associated with subsequent schizophrenia; moreover, people with schizophrenia who also use marijuana are more likely to have aggravated symptoms and more relapses (Johns, 2001). However, keep in mind the correlation between using marijuana and subsequent schizophrenia does not show that the drug *causes* schizophrenia. Perhaps marijuana use leads to schizophrenic symptoms only in those who were likely to develop the disorder anyway, or some aspect of a predisposition to develop schizophrenia also might make drug use attractive. It is also possible that marijuana “tips the scales” in those who are vulnerable but who would not develop schizophrenia if they did not use the drug. Or, perhaps some other factor affects both substance abuse and subsequent schizophrenia (Bowers et al., 2001). Researchers do not yet know enough to be able to choose among these possibilities, and true experiments designed to investigate them would obviously be unethical.

One study may be able to shed some light on the relationship between using marijuana and later developing schizophrenia: The study compared marijuana use by those who have a “predisposition” toward psychosis (e.g., a pattern of odd or paranoid thoughts) versus those who do not have such a predisposition (Henquet et al., 2005). The researchers began the study before any of the participants had developed the disorder, and thus they were able to examine marijuana use prior to emergence of the symptoms. The study not only found that marijuana use was associated with later development of psychosis, but also that it had a greater effect on those who were predisposed to develop schizophrenia. Moreover, the more extensively marijuana was used, the more likely psychosis was to develop. Finally, this study did not support the notion that those who are predisposed to develop schizophrenia use marijuana in an attempt to medicate themselves: Those who were predisposed were not more likely to use marijuana 4 years later.

Why might people with, or at risk for, schizophrenia be drawn to use marijuana at all? Glimmers of an answer come from a neuropsychological study of people with schizophrenia who used marijuana with varying frequencies. Those who used

Araldo Di Crollanza/Rex Features, Courtesy Everett Collection

Guitarist Peter Green (lying down), cofounder of the rock group Fleetwood Mac, developed schizophrenia after using LSD frequently. Although Green attributes his illness to his drug abuse, researchers cannot yet definitively state that such abuse *causes* schizophrenia in people who might not otherwise develop the disorder.

marijuana more frequently and more recently actually performed better on various neuropsychological tests, which suggests that marijuana use may enhance the cognitive functioning of people with schizophrenia (Coulston et al., 2007). Results from an fMRI study suggest that marijuana affects people with schizophrenia by increasing the activity of the frontal lobe, which counteracts some of the cognitive deficits and impaired brain functioning that can accompany the disorder (Callicott et al., 2003; Freedman, 2008).

Course

Typically, schizophrenia develops in phases. In the premorbid phase, before symptoms develop, some people may display personality characteristics that later evolve into negative symptoms. During the **prodromal phase**, which occurs before the onset of a psychological disorder, symptoms may develop gradually but do not meet all the criteria for the disorder. In the **active phase**, a person has full-blown positive and negative symptoms that meet all of the criteria for the disorder. Over time, the individual may fully recover, may have intermittent episodes, or may develop chronic symptoms that interfere with normal functioning.

Premorbid Phase

In the premorbid phase, a person who later goes on to develop schizophrenia may appear odd or eccentric and may have difficulty interacting with other people appropriately. This was the case for the Genain quads; during the premorbid phase, the sisters, with the possible exception of Myra, were seen as odd, and lacked the skills to make and sustain relationships with nonfamily members. However, it is important to note that most people who are odd or have eccentric tendencies do not develop schizophrenia. In addition, many people who develop schizophrenia, and particularly those who develop schizoaffective disorder, did not have odd or eccentric characteristics before the illness emerged.

Prodromal Phase

The prodromal phase, which may last from months to years, is marked by signs of suspiciousness, some disorganized thinking or behavior, poor hygiene, angry outbursts, and social withdrawal. These behaviors can be seen as precursors of the symptoms of schizophrenia, but they have not reached the level of positive and negative symptoms necessary for a diagnosis of schizophrenia (Heinssen et al., 2001; Maurer & Häfner, 1995).

The prodromal phase was a bit different for each Genain sister. Hester may have begun her prodromal phase as early as age 11, when her cognitive functioning was sufficiently impaired that she could no longer keep up in school and was held back. Moreover, even in elementary school, she was described as socially inept (Rosenthal, 1963; Mirsky et al., 2000). By 11th grade, her symptoms progressed to the point that she could no longer function well enough to attend school. In spring of that year, she was on her way to the active phase: “She complained of feeling insecure, was temperamental, began making sighing noises, clicking her tongue, and ‘hatefully’ combed her hair” (Rosenthal, 1963, p. 104). The tongue clicking and sighing continued for months, and she became destructive, breaking things. Instead of attending 12th grade, she stayed home, helping her mother around the house. Hester dressed and fed herself, but she was very slow at these tasks and would sometimes simply sit and stare into space.

In contrast, Nora’s prodromal symptoms emerged later. After high school, she was employed as a stenography clerk in the same building as her father’s office. However, after 1 year of working there, she began to have crying spells and increasing agitation. Her father criticized her for working too hard and told her to quit her job. During the time she held the job, Nora successfully fought off an attempted rape by a client of the company she worked for; her parents’ (and boss’s) response was that she should keep quiet about it and go on as if nothing happened. After that, she became increasingly agitated and disorganized until she quit her job several months later. Her illness progressed to the active phase; she developed

Prodromal phase

The phase that precedes the onset of a psychological disorder (such as schizophrenia) when symptoms do not yet meet all the criteria for the disorder.

Active phase

The phase of a psychological disorder (such as schizophrenia) in which the individual exhibits symptoms that meet all the criteria for the disorder.

psychotic symptoms, one of which was her complaint that the bones in her neck were slipping out of place.

Active Phase

During the active phase (which is also sometimes referred to as an *episode of schizophrenia* or *psychotic episode*), symptoms become full-blown, thereby meeting the diagnostic criteria for schizophrenia. It is usually positive symptoms that lead to the diagnosis. For up to 80% of people having a first episode of schizophrenia, the symptoms subside after treatment—they go into *remission* (Robinson et al., 1999).

However, for some people, the symptoms persist, even with medication; these patients are chronically ill. Approximately 60–70% of people who have had an episode of schizophrenia go on to have additional episodes (Torrey, 2001), but keep in mind that this also means that 30–40% of people who experience one episode never have another.

Middle-to-Late Phase

For people who continue to have active episodes of schizophrenia, cognitive functioning may decline significantly during the first 5 years of the illness; also, as they remain or become more disorganized, their ability to care for themselves declines. For example, they may reach a point where they cannot keep themselves properly groomed, or even dress themselves. However, by 10 years after the first episode, these people usually stabilize and seldom become worse. By 30 years after schizophrenia first developed, their functioning may have improved somewhat (see Table 12.4), particularly when some type of treatment has been effective. In fact, most of the Genain sisters improved (Mirsky et al., 2000). Iris and Nora were able to work part-time as volunteers; in their 40s and beyond, these two sisters were able to live outside of a hospital setting (Rosenthal, 1963; Mirsky et al., 2000).

Table 12.4 ▶ 10-Year and 30-Year Course of Schizophrenia

	10 Years Later	30 Years Later
Completely recovered	25%	25%
Much improved, relatively independent	25%	35%
Improved, but requiring extensive support network	25%	15%
Hospitalized, unimproved	15%	10%
Dead, mostly by suicide	10%	15%

Gender Differences

Men are somewhat more likely to develop schizophrenia than are women (McGrath, 2006) and do so at an earlier age. Specifically, men are more likely to develop the disorder between the ages of 18 and 25, whereas women are more likely to develop the disorder later in life, between the ages of 26 and 45. Compared to men, women usually have fewer negative symptoms of schizophrenia (Maric et al., in press; McGorry, 2001) and more mood symptoms (Maurer, 2001), and they are less likely to have substance abuse problems or to exhibit suicidal or violent behavior (Seeman, 2000). Moreover, women generally functioned at higher levels before their illness developed.

Culture

Two findings bear on the role of culture and schizophrenia. First, across various countries, schizophrenia is more common among people in urban areas and lower socioeconomic classes than among people in rural areas and higher socioeconomic classes (Freeman, 1994; Mortensen et al., 1999), as we'll discuss in more detail later in this chapter. Moreover, there are ethnic differences in prevalence rates in the United States: Blacks are twice as likely as Whites or Latinos to develop schizophrenia (Dassori et al., 1995; Keith et al., 1991). These prevalence differences may reflect the influence of a variety of moderating variables, such as social class and different rates of help seeking among the ethnic groups.

Second, people with schizophrenia in non-Western countries are generally better able to function in their societies than are their Western counterparts; that is, they have a better prognosis (American Psychiatric Association, 2000). We'll discuss

possible reasons for this finding in the *Understanding Schizophrenia* section on social factors.

Table 12.5 provides a summary of facts about schizophrenia.

Table 12.5 ▶ Schizophrenia Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Approximately 1% of people worldwide have schizophrenia (Gottesman, 1991; Tandon, Keshavan, & Nasrallah, 2008).
Comorbidity
<ul style="list-style-type: none"> Over 90% of people with schizophrenia also have another disorder. The most frequent comorbid disorders are mood, anxiety, and substance-related disorders.
Onset
<ul style="list-style-type: none"> Men are more likely to develop the disorder between 18 and 25, whereas women are more likely to develop it between 26 and 45 years old.
Course
<ul style="list-style-type: none"> About two thirds of people who have had one episode will go on to have subsequent episodes. About a third of people with schizophrenia become chronically ill, without much reduction of symptoms; for most others, the symptoms subside.
Gender Differences
<ul style="list-style-type: none"> Schizophrenia affects men more frequently than women (1.4:1 male-to-female ratio; McGrath, 2006), and—as noted above—women tend to develop the disorder at older ages than do men. Women have fewer negative symptoms than do men.
Cultural Differences
<ul style="list-style-type: none"> Schizophrenia is more common among those living in urban areas and those from lower socioeconomic groups (Freeman, 1994; Mortensen et al., 1999; Saha et al., 2005). In non-Western countries, people with schizophrenia generally function better in society than do those in Western countries (Hopper et al., 2007). In a given country, immigrants are almost twice as likely to develop schizophrenia as are native-born residents (Saha et al., 2005). Within the United States, Latinos and Whites are less likely to develop schizophrenia than are Blacks (Zhang & Snowden, 1999).
Source: Unless otherwise noted, citations for above table are: American Psychiatric Association, 2000.

Prognosis

In general, the long-term prognosis for schizophrenia follows the rule of thirds:

- one third of patients improve significantly;
- one third basically stay the same, having episodic relapses and some permanent deficits in functioning, but able to hold a “sheltered” job—a job designed for people with mild to moderate disabilities; and
- one third become chronically and severely disabled by their illness.

Table 12.6 summarizes factors associated with a better prognosis in Western countries. However, this table does not indicate a crucial fact about the prognosis for people with schizophrenia: Over the course of their lives, people with schizophrenia are more likely than others to die by suicide or to be victims of violence. Let’s examine these risks in greater detail.

Table 12.6 ▶ Factors Associated With a Better Prognosis for Individuals With Schizophrenia

People with schizophrenia who significantly improve often have one or more of the following characteristics:

- They functioned at a relatively high level before their first episode.
- The symptoms had a sudden onset.
- They developed symptoms later in life.
- They have a family history of mood disorders, not schizophrenia.
- They have the paranoid subtype (in the DSM-IV-TR categorization) or the nondescript subtype, with relatively good cognitive functioning.
- They have fewer negative symptoms.
- They are aware of their symptoms and recognize that the symptoms are caused by an illness.
- They are women (whose symptoms also respond better to medication).

Sources: Amador et al., 1991; Fenton & McGlashan, 1994; Green, 2001.

Suicide

People with schizophrenia have a higher risk of dying by suicide than do other people: As Table 12.4 shows, 10–15% of people with schizophrenia commit suicide (Caldwell & Gottesman, 1990; Siris, 2001). Those with the paranoid subtype are at the highest risk for suicide. Perhaps paradoxically, patients at risk for committing suicide are those who are most likely to be aware of their symptoms: They have relatively few negative symptoms but pronounced positive symptoms; they are highly intelligent with career goals, are aware of their deterioration, and have a pattern of relapsing and then getting better, with many episodes; and—like other people who die by suicide—they are more likely to be male (Fenton, 2000; Funahashi et al., 2000; Moussaoui et al., 1999; Siris, 2001). Ironically, some of these factors—a high level of premorbid functioning, few negative symptoms, and an awareness of the symptoms and their effects—are associated with a better prognosis (see Table 12.6). As researchers have identified these risk factors, they have used them to focus suicide prevention efforts.

Violence

Suicide is often the result of some form of self-inflicted violence, but this does not imply that patients with schizophrenia are generally violent. Although the afflicted individual may threaten to become violent during an episode of schizophrenia, contrary to sensational headlines, these patients rarely actually engage in violent behavior. Risk factors associated with violent behavior include being male, having comorbid substance abuse, not taking medication, and having engaged in criminal behavior or having had psychopathic tendencies before schizophrenia developed (Hunt et al., 2006; Monahan et al., 2001; Skeem & Mulvey, 2001; Tengström, Hodgins, & Kullren, 2001). Only one of these factors pertains to schizophrenia directly; rather, it is the comorbid disorders that increase the risk of violent behavior (Angermeyer, 2000; Erkiran et al., 2006; Swanson et al., 2006). Note that less than 10% of violent acts reported to the police are caused by people with schizophrenia, and most of these offenders are people with schizophrenia who also abuse alcohol or drugs (Walsh, Buchanan, & Fahy, 2002).

Rather than being perpetrators of violence, people with schizophrenia have a much greater likelihood of being victims of violence. One survey found that almost 20% of people with a psychotic disorder had been victims of violence in the previous 12 months. Those who were more disorganized and functioned less well were more likely to have been victimized (Chapple et al., 2004), perhaps because their impaired functioning made them easier “marks” for perpetrators.

Key Concepts and Facts About What are Schizophrenia and Other Psychotic Disorders?

- According to DSM-IV-TR, schizophrenia is characterized by two or more symptoms, at least one of which must be positive; these symptoms must be present for a minimum of 6 months and must significantly impair functioning.
- Positive symptoms are delusions, hallucinations, disorganized speech, and disorganized behavior. However, research findings suggest that the disorganized symptoms form their own distinct cluster and should be grouped separately from delusions and hallucinations.
- Negative symptoms are flat affect, alogia, and avolition.
- Research studies have indicated that cognitive deficits underlie negative and disorganized symptoms of schizophrenia. Such deficits include problems with attention, working memory, and executive functioning. The DSM-IV-TR criteria have been criticized for omitting important cognitive and social deficits that lead to positive and negative symptoms and that are closely associated with prognosis.
- DSM-IV-TR distinguishes five subtypes of schizophrenia: paranoid, disorganized, catatonic, undifferentiated, and residual schizophrenia. However, because the symptoms of schizophrenia often shift over time, an individual's subtype can change. Many researchers argue that a more meaningful way to distinguish subtypes of schizophrenia would be based on whether the individual has a deficit or nondeficit subtype.
- Symptoms of schizophrenia can appear to overlap with those of other disorders, notably mood disorders and substance-related disorders. The category of psychotic disorders specifically requires symptoms of hallucinations or delusions; disorders in this category are schizophrenia, schizophreniform disorder, brief psychotic disorder, schizoaffective disorder, delusional disorder, and shared psychotic disorder. These disorders, along with schizotypal personality disorder, are part of a spectrum of schizophrenia-related disorders.
- Schizophrenia occurs in approximately 1% of the population worldwide, and most people with schizophrenia have at least one comorbid disorder. Men have an earlier onset of the disorder than do women. Symptoms of the disorder typically evolve in phases: premorbid, prodromal, active, and then middle-to-late phases.
- Up to 15% of people with schizophrenia commit suicide. People with this disorder who behave violently are most likely to have a comorbid disorder that is associated with violent behavior, such as a substance-related disorder. People with schizophrenia are more likely than other people to be victims of violence.

Making a Diagnosis

- Reread Case 12.1 about Emilio, and then determine whether or not his symptoms met the minimum criteria for a diagnosis of schizophrenia. Specifically, list which criteria apply and which ones do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision? If you decide that a diagnosis of schizophrenia is appropriate for Emilio, do you think he has the deficit or nondeficit subtype, and why?

Understanding Schizophrenia

Despite the low odds that all four of the Genain quads would develop schizophrenia, it did happen. Why? The neuropsychosocial approach helps us to understand the factors that lead to schizophrenia and how these factors influence each other. As we shall see, although neurological factors (including genes) can make a person vulnerable to the disorder, psychological and social factors also contribute to its development—which may help explain not only why all four Genain quads ended up with schizophrenia, but also why the disorder affected them differently.

The quads shared the same genes, looked alike, and at least in their early years, were often treated similarly, especially by Mrs. Genain. However, Hester was smaller and frailer than the others; she weighed only 3 pounds at birth and could not always keep up with her sisters. Because of Hester's difficulties, it wasn't always possible to treat the four girls the same, and so Mr. and Mrs. Genain sometimes treated them as two pairs of twins: Nora and Myra were paired together (they were seen as most competent), and Iris—who in fact was almost as competent as Nora and Myra—was paired with Hester.

Let's look at the specific neurological, psychological, and social factors that give rise to schizophrenia and then examine how these factors affect one another.

Neurological Factors in Schizophrenia

Perhaps more than for any other psychological disorder, neurological factors play a crucial role in the development of schizophrenia. These factors involve brain systems, neural communication, and genetics.

Brain Systems

People who have schizophrenia have abnormalities in the structure and function of their brains. Early research on this topic came from autopsy studies in which researchers compared the brains of people who had schizophrenia with those of people who did not (Rosanoff, 1914; Southard, 1910). These researchers found that the brains of people who had schizophrenia were atrophied (shrunk) relative to the brains of people without the disorder. Neuroimaging studies have since documented more specific differences in brain structure and function between those with schizophrenia and those who do not have the disorder.

The most striking example of a structural abnormality in the brains of people with schizophrenia is enlarged ventricles, which are cavities in the center of the brain that are filled with cerebrospinal fluid (Vita et al., 2006). Larger ventricles means that the size of the brain itself is reduced. This reduction in size is especially significant for people with schizophrenia because, in general, even before developing the disorder, they have brains that are smaller than normal. This is true, in part, because their brains never grew to “full” size. In addition, research suggests that schizophrenia causes parts of the brain to shrink (DeLisi et al., 1997; Gur, Ragland, & Gur, 1997; Rapoport et al., 1999).

One possible reason for the differences in brain structure (and brain functioning) between those who have schizophrenia and those who do not could be effects of the medications used to treat schizophrenia—and not the disorder itself. With the development of neuroimaging techniques, scientists began to address this possibility. Researchers used longitudinal studies to follow people from the time of their first schizophrenic episode. Such studies have shown that even at the time of their first episode, people who have schizophrenia have smaller overall brain volume and less cerebral cortex than people who have no known risk of developing schizophrenia (Velakoulis et al., 1999). In fact, the less cortical matter patients had, the more poorly they fared 2 years after their first episode (Cahn et al., 2002). Thus, these abnormalities in brain structure are not primarily a result of taking medication.

In 1981, the Genain sisters, then 51 years old, returned to NIMH for a 3-month evaluation; during that time they were taken off their medications. CT scans of the quads showed similar brain abnormalities in all four sisters (Mirsky & Quinn, 1988). However, even though they were basically genetically identical, their performance on neuropsychological tests varied: Nora and Hester showed more evidence of neurological difficulties, and they were more impaired in their daily functioning when not taking medication. Thus, once again, we see that genes are not destiny and that brain function cannot be considered in isolation. The brain is a mechanism, but how it performs depends in part on how it is “programmed” by learning and experience—which are psychological factors.

In the following sections, we consider the likely role of the following brain abnormalities: a frontal lobe defect, an impaired temporal lobe and thalamus, an abnormal hippocampus, and abnormal interactions among brain areas. We then turn to possible causes of such abnormalities in the brain, considering the effects of the mother’s diet or illness, as well as early oxygen deprivation. Finally, we examine possible “biological markers”; telltale neurological, bodily, or behavioral signs that may indirectly reveal that a person is vulnerable to developing schizophrenia.

These brain scans of identical twins show, for one of them, the enlarged ventricles that typically are associated with schizophrenia. The twin on the right has schizophrenia, the twin on the left does not.

A Frontal Lobe Defect?

Many studies have set out to discover whether people with schizophrenia have impaired frontal lobe functioning. The root of such impairment may lie in the fact that the brain has too many connections among neurons at birth, and part of normal maturation is the elimination, or *pruning*, of unneeded connections (Huttenlocher, 2002). Results suggest that an excess of such pruning takes place during adolescence for people who develop schizophrenia: Too many of the neural connections in the frontal lobes are eliminated, which may account for some of the neurocognitive deficits that typically accompany this disorder (Keshavan, Anderson, & Pettegrew, 1994; Pantelis et al., 2003; Walker et al., 2004).

In addition, some symptoms of schizophrenia are associated with abnormal activity in specific brain areas; for example, people with schizophrenia often have too little activity in part of the left frontal lobe, a lack that is associated with avolition. Moreover, studies have shown that disorganized symptoms are associated with abnormal activity in the right frontal lobe (Liddle et al., 1992; Perlstein et al., 2001).

Impaired Temporal Lobe and Thalamus?

Enlarged ventricles are associated with decreased size of the temporal lobes. This is significant for people with schizophrenia because the temporal lobes process auditory information, some aspects of language, and visual recognition (Levitin, Ward, & Catt, 1999; Sanfilipo et al., 2002). Abnormal functioning of the temporal lobes may underlie some positive symptoms, notably auditory hallucinations, in people with schizophrenia.

The thalamus, which transmits sensory information to other parts of the brain, also appears to be smaller and to function abnormally in people with schizophrenia (Andreasen et al., 1994; Andrews et al., 2006; Konick & Friedman, 2001). Abnormal functioning of the thalamus is associated with difficulties in focusing attention, in distinguishing relevant from irrelevant stimuli, and in particular types of memory difficulties, all of which are cognitive deficits that can arise with schizophrenia.

Abnormal Hippocampus?

The hippocampus—a subcortical brain structure crucially involved in storing new information in memory—has also been a focus of schizophrenia research. Studies have found that the hippocampi of people with schizophrenia and their first-degree relatives (parents and siblings) are smaller than those of control participants (Nelson et al., 1998; Seidman et al., 2002; Vita et al., 2006), which may contribute to the deficits in memory often experienced by some people with schizophrenia (Holthausen et al., 2003; Olson et al., 2006; Yoon et al., 2008).

Interactions Among Brain Areas

Some researchers propose that schizophrenia arises from disrupted interactions among the frontal lobes, the thalamus, and the cerebellum—which may act as a time-keeper, synchronizing and coordinating signals from many brain areas (Andreasen, 2001; Andreasen et al., 1999). According to this theory, the thalamus fails to screen out sensory information, which overwhelms subsequent processing, and the form and content of the person's thoughts become confused. In addition, many patients with schizophrenia have abnormal interconnections between the anterior cingulate cortex in the frontal lobe (which is involved in attention) and the hippocampus (Benes, 2000), which may contribute to some of the disrupted cognitive functions.

Possible Causes of Brain Abnormalities

How might these brain abnormalities arise? Researchers have identified several possible causes. Some researchers have focused on factors that could affect the developing brain of a fetus or a newborn. The growing fetus can be affected if the mother is malnourished. Similarly, development of the brain can be disrupted if the mother is significantly ill during her pregnancy. In addition, the brain can become impaired if oxygen is cut off from the infant before or during birth. Let's consider each of these possible causes.

Maternal Malnourishment One possible cause of brain abnormalities is *maternal malnourishment* during pregnancy, particularly during the first trimester (Brown et al., 1999; Wahlbeck et al., 2001). It is possible, for example, that Mrs. Genain's poor diet contributed to the quads' schizophrenia: During the first trimester of

her pregnancy, Maud Genain had such bad nausea that her weight dropped from 150 pounds before her pregnancy to 117 pounds a few months into her pregnancy (Rosenthal, 1963). However, we must note that the research results are based on data from many people, and thus we must always be careful when applying data from a group (the members of which varied) to specific individuals (the Genains).

Maternal Illness and Stress A second possible cause of brain abnormalities is *maternal illness* (Brown et al., 2004; Buka et al., 1999; Ellman, 2008; Mednick et al., 1998). Maternal illness during the 6th month of pregnancy is of particular concern. During fetal development, neurons travel to their final destination in the brain and establish connections with other neurons (this process is called *cell migration*). If the mother catches the flu or another viral infection in the second trimester, this may disrupt cell migration in the developing fetus's brain, which causes some neurons to fall short of their intended destinations. Because the neurons are not properly positioned, they form different connections than they would have formed if they had been in the correct locations—leading to abnormal neural communication (Arnold et al., 1991; David, 1994; Green, 2001; McGlashan & Hoffman, 2000). The cognitive deficits associated with schizophrenia could be related to such abnormalities in cell migration: Various brain areas may not be set up properly to allow smooth communication within and among them. However, among those who have no family history of schizophrenia or related disorders, maternal malnutrition or illness accounts for only a small percentage of cases of schizophrenia (Green, 2001).

Significant maternal stress in the first trimester (such as the death of the mother's parent) has also been associated with higher rates of schizophrenia in the children (Ellman, 2008; Khashan et al., 2008).

Oxygen Deprivation Another possible source of the abnormal brain structure and function found in schizophrenia is prenatal or birth-related medical complications that lead to oxygen deprivation (Cannon, 1997, 1998; Geddes & Lawrie, 1995; McNeil, Cantor-Graae, & Weinberger, 2000; Zornberg, Buka, & Tsuang, 2000). Studies have shown that people with schizophrenia who did not receive enough oxygen at specific periods before birth have smaller hippocampi than do people with schizophrenia who were not deprived of oxygen during or before birth (van Erp et al., 2002). As noted earlier, the hippocampus plays a role in memory, and thus a reduced size of this brain structure may help explain some of the problems with working memory that can arise in people with schizophrenia.

Although inadequate oxygen before or during birth may contribute to making a person vulnerable to schizophrenia, it does not cause the disorder. A relatively large number of infants experience this problem during birth and do not go on to develop schizophrenia (Clarke, Harley, & Cannon, 2006).

Biological Markers

People with schizophrenia, and even some of their unaffected family members, may exhibit distinctive behaviors in specific situations or when performing specific tasks—behaviors that are not displayed by other people. When a neurological, bodily, or behavioral characteristic distinguishes people with a psychological disorder (or people with a first-degree relative with the disorder) from people who do not have the disorder, it is said to be a **biological marker** for the disorder. One biological marker for schizophrenia, but not other psychological disorders, is difficulty in maintaining smooth, continuous eye movements when tracking a light as it moves across the visual field—such tracking is called *smooth pursuit eye movements* (Clementz & Sweeney, 1990; Holzman et al., 1984; Iacono et al., 1992). This difficulty reflects underlying neurological factors, and is associated with irregularities in brain activation during motion processing (Hong et al., 2005). Although it is not clear exactly why people with schizophrenia and their family members have this specific difficulty (Holzman et al., 1988), researchers believe that it can help to identify people who are vulnerable for developing schizophrenia. Figure 12.4 shows the results of smooth pursuit eye movement recordings for the Genain sisters.

Biological marker

A neurological, bodily, or behavioral characteristic that distinguishes people with a psychological disorder (or a first-degree relative with the disorder) from those without the disorder.

Figure 12.4

12.4 ► Genain Sisters' Smooth Pursuit Eye Movements

The Genain sisters completed this test in 1981. The results show that Nora and Hester had more irregularities in their eye movements and they also performed more poorly on some of the neuropsychological tests, indicating that they were more neurologically impaired.

The child in this photo went on to develop schizophrenia. Notice the unusual hand postures (indicating involuntary movement) of the child; studies of home movies of the child who later developed schizophrenia revealed many such involuntary movements, particularly of the tongue, lips, or arms.

Another biological marker for schizophrenia is *sensory gating* (Freedman et al., 1996), which is assessed as follows: Participants hear two clicks, one immediately after the other. Normally, the brain responds less strongly to the second click than to the first. However, people with schizophrenia and their first-degree relatives don't show the normal large drop in the brain's response to the second click. This has been interpreted as a manifestation of the difficulties that people with schizophrenia can have in filtering out unimportant stimuli.

A third type of biological marker for schizophrenia has been reported by researchers who performed careful analyses of home movies of children who were later diagnosed with schizophrenia (Grimes & Walker, 1994; Walker et al., 1993). They found that the children who went on to develop schizophrenia were different from their siblings: They made more involuntary movements, such as writhing or excessive movements of the tongue, lips, or arms. This tendency for involuntary movement was particularly evident from birth to age 2, but could be seen even through adolescence in individuals who later developed the disorder (Walker, Savoie, & Davis, 1994). Moreover, those who displayed more severe movements of this type later developed more severe symptoms of schizophrenia (Neumann & Walker, 1996).

These researchers also found that the children who displayed more involuntary movements also cried more when coming into contact with adults. Similar results were reported by researchers who studied Finnish people with schizophrenia. Looking back at the patients' school performance, these researchers found that the children who went on to develop schizophrenia did not do significantly worse academically than other children—but they were significantly worse at sports and handicrafts, both of which require motor coordination (Cannon et al., 1999). Further support for the relationship between movement abnormalities and schizophrenia comes from a study in which researchers compared the extent of abnormal movements in two groups of people: One group consisted of people with schizotypal personality disorder—a disorder on the schizophrenia spectrum—and the other group was composed of healthy control participants or people who had another type of personality disorder. Only people with schizotypal personality disorder had abnormal movements (Mittal et al., 2008).

This said, we note that not everyone who is clumsy or uncoordinated goes on to develop schizophrenia. Biological markers are correlated with underlying problems—but sometimes can also arise for other reasons.

Neural Communication

Schizophrenia is likely to involve a complex interplay of many brain systems and neurotransmitters, including dopamine, serotonin, and glutamate, as well as the stress hormone, cortisol. Let's look more closely at these neurotransmitter substances and their interactions, as well as the possibility that sex hormones may play a role in this disorder.

Dopamine

One neurotransmitter that is clearly involved in schizophrenia is dopamine: Neuroimaging studies of people with schizophrenia have found abnormally low numbers of dopamine receptors in their frontal lobes (Okubo et al., 1997), as well as increased production of dopamine (possibly to compensate for the reduced numbers of receptors in the frontal lobes) in the striatum (parts of the basal ganglia that produce dopamine; Heinz, 2000). The **dopamine hypothesis** proposes that an overproduction of dopamine or an increase in the number or sensitivity of dopamine receptors is responsible for schizophrenia. According to this hypothesis, the excess dopamine or extra sensitivity to this neurotransmitter triggers a flood of unrelated thoughts, feelings, and perceptions. Delusions are then attempts to organize these disconnected events into a coherent, understandable experience (Gottesman, 1991; Kapur, 2003). This hypothesis was supported by the discovery that medications that decrease dopamine levels also reduce the positive symptoms of schizophrenia (but not the negative symptoms; Rosenbaum et al., 2005). Further support for the dopamine hypothesis comes from studies of people who do not have schizophrenia: When they are given LSD, an hallucinogenic that increases dopamine activity (as well as blocking the

Dopamine hypothesis

The view that schizophrenia arises from an overproduction of dopamine or an increase in the number or sensitivity of dopamine receptors.

neurotransmitter serotonin), they report schizophrenia-like experiences (Syvalathi, 1994). (As noted in Chapter 9, LSD affects both serotonin and dopamine activity.)

Clearly, dopamine is involved in schizophrenia, but research has definitively documented that the dopamine hypothesis was an oversimplification (McDermott & de Silva, 2005). Rather than being a primary cause of the disorder, dopamine affects, and is affected by, other neurotransmitters whose activity, along with the structural and functional abnormalities of various brain areas, gives rise to some of the symptoms of schizophrenia (Laruelle et al., 1993; Nestler, 1997; Syvalathi, 1994; Vogel et al., 2006; Walker & Diforio, 1997; Weinberger & Lipska, 1995).

Serotonin and Glutamate

Medications that affect serotonin levels can decrease both positive and negative symptoms in people with schizophrenia. Research studies suggest complex interactions among serotonin, dopamine, and glutamate (Andreasen, 2001). For example, serotonin has been shown to enhance the effect of glutamate, which is the most common fast-acting excitatory transmitter in the brain (Aghajanian & Marek, 2000). This is relevant to understanding schizophrenia because the N-methyl-D-aspartate (NMDA) glutamate receptor has been shown to play a crucial role in learning and memory, and hence abnormalities in its functioning may explain some of the deficits associated with schizophrenia, such as deficits in working memory. In particular, studies have found unusually high levels of glutamate in people with schizophrenia, particularly in the frontal lobe (Abbott & Bustillo, 2006; van Elst et al., 2005); such an excess of glutamate may disrupt the timing of neural activation in the frontal lobe, which in turn may impair cognitive activities that depend on the smooth coordination of different operations, such as working memory, where information must be actively retained in short-term memory as it is operated upon (Lewis & Moghaddam, 2006).

Stress and Cortisol

Research findings suggest that stress can contribute to schizophrenia, because stress affects cortisol production, which in turn affects the brain; the effects of stress probably start well before the first episode of schizophrenia emerges. The relationship with cortisol appears even in childhood. Children who are at risk for schizophrenia react more strongly to stress, and their baseline levels of cortisol are higher than those of other children (Walker, Logan, & Walker, 1999). The relationship between stress, cortisol, and symptoms of schizophrenia has also been noted during adolescence, the time when prodromal symptoms often emerge: A 2-year longitudinal study of adolescents with schizotypal personality disorder found that cortisol levels—and symptoms of schizophrenia—increased over the 2 years (Walker, Walder, & Reynolds, 2001).

Thus, people who develop schizophrenia appear to be more biologically reactive to stressful events. A hypothesized mechanism for this relationship is that the biological changes and stressors of adolescence promote higher levels of cortisol, which is thought to affect dopamine activity. Even after adolescence, people with schizophrenia have higher levels of stress-related hormones, including cortisol (Zhang et al., 2005). In one study, the siblings of people with schizophrenia exhibited a larger stress response than did healthy control participants but a smaller stress response than did participants with schizophrenia; these findings not only provide evidence that genes play a role in how strongly a person will respond to stress, but also suggest that the genetic contribution to the stress response may play a role in the development of schizophrenia (Brunelin et al., 2008).

Effects of Estrogen

We noted earlier that when women develop schizophrenia, they often have different symptoms than men do and tend to function better. Such findings have led to the *estrogen protection hypothesis* (Seeman & Lang, 1990). According to this hypothesis, the hormone estrogen, which occurs at higher levels in women, protects against symptoms of schizophrenia through its effects on serotonin and dopamine activity. This protection may explain why women are likely to have a later onset of the disorder than do men. Evidence for the estrogen protection hypothesis comes from two sources. One is

the finding that women with schizophrenia who had higher levels of estrogen also had better cognitive functioning (Hoff et al., 2001). The other is the finding that providing constant doses of estrogen through a skin patch (in addition to antipsychotic medication) reduced the positive symptoms of women with severe schizophrenia more than did antipsychotic medication without supplementary estrogen (Kulkarni et al., 2008).

Genetics

Various twin, family, and adoption studies indicate that genes play a role in schizophrenia (Gottesman, 1991; Kendler & Diehl, 1993; Tienari, Wahlberg, & Wynne, 2006; Wynne et al., 2006). The more genes that a person shares with a relative who has schizophrenia, the higher the risk that that person will also develop schizophrenia (see Table 12.7). However, even for those who have a close relative with schizophrenia, the chance of developing the disorder is still relatively low: More than 85% of people who have one parent or one sibling (who is not a twin) with the disorder do not go on to develop it themselves (Gottesman & Moldin, 1998), and this percentage is even lower for people with a grandparent, aunt, or uncle (second-degree relatives) with the disorder (Gottesman & Erlenmeyer-Kimling, 2001). Nonetheless, a family history of schizophrenia is still the strongest known risk factor for developing the disorder (Hallmayer, 2000).

If the cause of schizophrenia were entirely genetic, then when one identical twin developed the disorder, the co-twin would also develop the disorder; that is, the co-twin's risk of developing schizophrenia would be 100%—if schizophrenia were entirely caused by genes. But this is not what happens; the actual risk of a co-twin developing schizophrenia ranges from 46 to 53% (in different studies), as shown in Table 12.7.

However, identical twins have the same *predisposition* for developing schizophrenia, although only one of them may develop it. This means that even if only one twin in a pair develops the disorder, the children of both twins (the one with the disorder and the one without) have the same

risk of developing it. That is, both the affected and the unaffected twin transmit the same genetic vulnerability to their offspring (Gottesman & Bertelsen, 1989).

Another risk factor that may be related to genes does not involve the usual patterns of inheritance, but may hinge on genetic defects in the sperm of older fathers (Tsuchiya et al., 2005; Wohl & Gorwood, 2007; Zammit et al., 2003): Children whose fathers were over 45 years old when they were born were almost three times as likely to develop schizophrenia as children whose fathers were between the ages of 20 and 24 when they were born. One possibility is that mutations in the sperm of older fathers may be responsible for this increased rate, but there is no solid evidence yet that such mutations are in fact responsible for this effect.

Researchers have begun to make inroads in identifying specific genes that create various vulnerabilities for schizophrenia (Craddock, O'Donovan, & Owen, 2005; Stefansson et al., 2008; Xu et al., 2008). However, the results of studies that examine specific genes thought to be related to schizophrenia have generally been disappointing—any given gene accounts for only a small minority of cases of schizophrenia (Hamilton, 2008; Sanders et al., 2008). Nevertheless, some aspects of the disorder have been linked to specific genes; for example, some patients with schizophrenia exhibit symptoms of agitation, and a specific mutation of one gene has been linked to this symptom (Sachs, 2006).

Clearly, genes alone do not determine whether someone will develop schizophrenia. In order to examine the influences of both genes and environment, a Finnish adoption study tracked two groups of adopted children: those whose biological mothers had schizophrenia, and those whose mothers did not (the control group). None of the adoptive parents of these children had schizophrenia, but some adoptive families were dysfunctional (Tienari et al., 1994, 2006). In the control group, the incidence of schizophrenia was no higher than in the general population, regardless of the characteristics of the adoptive families. In contrast, the children whose biological mothers had schizophrenia and whose adoptive families were dysfunctional were much more likely

Table 12.7 ▶ Degree of Relatedness and Risk of Developing Schizophrenia

Family Member(s) with Schizophrenia	Risk of Developing Schizophrenia
First cousin	2%
Half-sibling	6%
Full sibling	9%
One parent	13%
Two parents	46%
Fraternal twin	14–17%
Identical twin	46–53%
Sources: Gottesman, 1991; Kendler, 1983.	

to develop schizophrenia than were the children whose biological mothers had schizophrenia but whose adoptive families were not dysfunctional. Thus, better parenting appeared to protect children who were genetically at risk for developing schizophrenia.

Psychological Factors in Schizophrenia

We have seen that schizophrenia is not entirely a consequence of brain structure, brain function, or genetics. As the neuropsychosocial approach implies, schizophrenia arises from a combination of different sorts of factors. For example, the neurocognitive deficits that plague individuals with schizophrenia also affect how they perceive the social world, and their perceptions affect their ability to function in that world (Sergi et al., 2006). If we understand their experiences, their behaviors do not appear so bizarre. Let's examine in detail the psychological underpinnings of schizophrenia so that we can better understand how all four Genain quadruplets developed the disorder, despite the odds against this outcome. Note that not every person with schizophrenia experiences each type of difficulty we discuss (Walker et al., 2004).

Mental Processes and Cognitive Difficulties: Attention, Memory, and Executive Functions

We've already noted problems with attention, working memory, and executive function in schizophrenia. Let's now consider how such problems may contribute to the disorder.

The cognitive difficulties of people with schizophrenia arise before the DSM-IV-TR symptoms emerge, and the difficulties persist even after the DSM-IV-TR symptoms have diminished (Hughes et al., 2003; Rund et al., 2004). The difficulties with attention—in distinguishing relevant from irrelevant stimuli, for example (Nuechterlein, 1991)—occur even when the person is taking medication and isn't psychotic (Cornblatt et al., 1997; Dawson et al., 1993). This attentional problem can make it hard for individuals with schizophrenia to discern which stimuli are important and which aren't; such individuals may feel overwhelmed by a barrage of stimuli. This leads to problems in organizing what they are perceiving and experiencing, which would contribute to their difficulties with perception and memory (Sergi et al., 2006).

Furthermore, as noted earlier, problems with working memory lead people with schizophrenia often to exhibit deficits in problem solving, planning, judgment, and other executive functions. It may be hard for them to plan and complete the various steps of a multistep task, such as making mashed potatoes.

Another cognitive problem common to people with schizophrenia is that they often don't realize that they are having problems; this inability is referred to as a *lack of insight*. They do not recognize that they are behaving abnormally or having unusual experiences. Thus, they are unaware of their disorder or the specific problems it creates for themselves and others (Amador & Gorman, 1998) and see no need for treatment (Buckley, Wirshing et al., 2007). In Case 12.2, psychologist Fred Frese discusses his lack of insight into his own schizophrenia and its effects.

CASE 12.2 ► FROM THE INSIDE: Schizophrenia

Psychologist Fred Frese describes his history with schizophrenia:

I was 25 years old, and I was in the Marine Corps at the time, and served two back to back tours in the Far East, mostly in Japan. And when I came back I was a security officer in charge of a Marine Corps barracks with 144 men. And we had responsibilities for security for atomic weapons . . . and a few other duties. About six months into that assignment, I made

continued on next page

Performance in a virtual maze classified people with symptoms of schizophrenia versus healthy controls. Participants had to remember which combination of three features—color, shape, and sound—would open each door in the maze. Participants who did poorly also reported more symptoms of schizophrenia—both positive and negative (Sorkin et al., 2006).

Sorkin, A., Weinshall, D., Modai, I., & Peled, A. (2006). Improving the accuracy of the diagnosis of schizophrenia by means of virtual reality. *American Journal of Psychiatry*, 163, 512–520. Reprinted with permission from the American Journal of Psychiatry.

Psychologist Fred Frese was diagnosed with paranoid schizophrenia in 1965 when he was a Marine Corps security officer. He was hospitalized many times over the next 10 years but was able to earn a Ph.D. in psychology in 1978. Over the past 30 years, he has written about mental illness from both sides of the experience, been an advocate for the mentally ill, and served as Director of Psychology at Western Reserve Psychiatric Hospital.

a discovery—to me it was a discovery—that somehow the enemy had developed a new weapon by which they could psychologically hypnotize certain high-ranking officials. And I became very confident that I had stumbled onto this discovery. And because it was a psychological sort of thing I would share this with a person who would be likely to know most about this kind of stuff and that was the base psychiatrist. So I called him up and he agreed to see me right away, and I went down and told him about my discovery, and he listened very politely and when I got finished to get up and leave there were these two gentlemen in white coats on either side of me—either shoulder. And I often say I think one of them looked like he might be elected governor of Minnesota somewhere along the way. But they escorted me down into a seclusion padded room [sic]. And within a day or two I discovered that they had me labeled as paranoid schizophrenic. Of course I immediately recognized that the psychiatrist was under the control of the enemies with their new weapons. I spent about five months mostly in Bethesda, which is the Navy's major hospital, and was discharged with a psychiatric condition. However, that was my discovery that I was diagnosed with . . . schizophrenia. The way the disorder works is, I didn't have a disorder, I had "made this discovery". So it was a number of years before I came to this conclusion that there was something wrong here and I was hospitalized about ten times, almost always involuntarily . . . over about a ten year period of time.

(WCPN, 2003).

To develop a sense of the consequences of having such cognitive difficulties, imagine the experience of a man with these deficits who tries to go shopping for ingredients for dinner. He may find himself in the supermarket, surrounded by hundreds of food items; because of his attentional problems, each item on a shelf may capture the same degree of his attention. Because of deficits in executive functioning, he loses track of why he is there—what was he supposed to buy? And if he remembers why he is there ("I need to get chicken, rice, and vegetables"), he may not be able to exercise good judgment about how much chicken to buy or which vegetables. Or, because of the combination of his cognitive deficits, he may find the whole task too taxing and leave without the dinner ingredients.

Beliefs and Attributions

As mentioned earlier, cognitive difficulties often develop before symptoms of schizophrenia emerge. The early influence of the cognitive deficits affects what the person comes to believe. For example, because children with these cognitive deficits may do poorly in school and often are socially odd, they may be ostracized or teased by their classmates; they may then come to believe that they are inferior and proceed to act in accordance with those beliefs, perhaps by withdrawing from others (Beck & Rector, 2005).

In addition, if people with schizophrenia have delusional beliefs, the delusions almost always relate to themselves and their extreme cognitive distortions (e.g., "The FBI is out to get me"). These distortions influence what they pay attention to and what beliefs go unchallenged. People with schizophrenia may be inflexible in their beliefs or may jump to conclusions, and their actions based on their beliefs can be extreme (Garety et al., 2005). Moreover, they may be very confident that their (false) beliefs are true (Moritz & Woodward, 2006). For example, a man with paranoid schizophrenia might attribute a bad connection on a cell phone call to interference by FBI agents or aliens; he searches for and finds "confirming evidence" of such interference ("There's a bad connection when I call my friend and they want to listen in, but there's no static when I call directory assistance and there's no need for them to listen in"). Disconfirming evidence—that cell phone service is weak in the spot where he was standing when he made the call to his friend—is ignored (Beck & Rector, 2005).

People with paranoid schizophrenia tend to blame negative events on others, specifically the subjects of their delusions (Garety & Freeman, 1999). So, for instance, if a man with paranoid schizophrenia is waiting for a commuter train and hears an announcement that the train is delayed, he might think, "The FBI is trying

to prevent me from reaching my destination, and they've instructed the transit system to delay my train." People with paranoid schizophrenia are often unwilling to test the veracity of their beliefs, perhaps believing that such tests would be "rigged" and the results therefore meaningless.

Similarly, people with schizophrenia who have auditory hallucinations do not generally try to discover where the sounds of the hallucinations are coming from. For example, they don't check whether the radio is on or whether people are talking in the hallway. They are less likely to question the reality of an unusual experience (that is, whether it arises from something outside themselves) and so do not correct their distorted beliefs (Johns, Hemsley, & Kuipers, 2002).

Negative symptoms can also give rise to unfounded beliefs; specifically, people who have negative symptoms are particularly likely to have low expectations of themselves. Although such low expectations could indicate an accurate assessment of their abilities, research suggests that this is generally not the case: When cognitive therapy successfully addresses the negative self-appraisals of people with schizophrenia, their functioning subsequently improves (Rector, Seeman, & Segal, 2003). This finding suggests that the negative self-appraisals are distorted beliefs that became self-fulfilling prophecies (Beck & Rector, 2005).

Emotional Expression

Another psychological factor is the facial expressions of people with schizophrenia, which are less intense than those of people who do not have the disorder (Brozgold et al., 1998; Kring & Neale, 1996). Moreover, people with schizophrenia are less accurate than control participants in labeling the emotions expressed by faces they are shown (Penn & Combs, 2000; Schneider et al., 2006). Part of the explanation for problems related to emotional expression may be the cognitive deficits: In general, people with schizophrenia often have difficulty recognizing emotions that are conveyed by tone of voice (such as the quaver in a voice filled with fear), facial expression (such as an annoyed frown), or body language (such as a defensive, withdrawn crossing of the arms; Green, 2001). Because they cannot "read" nonverbal communication well, they are confused when someone's words and subsequent behavior are at odds. People with schizophrenia are likely to miss the nonverbal communication that helps most people make sense of the apparent inconsistency between what others say and what they do (Greig, Bryson, & Bell, 2004). In fact, even biological relatives of people with schizophrenia have problems in understanding other people's nonverbal communication (Janssen et al., 2003), which suggests that neurological factors are involved.

Social Factors in Schizophrenia

We've seen that schizophrenia often entails difficulty in understanding and navigating the social world. We'll now examine this difficulty in more detail and also consider the ways that economic circumstances and cultural factors can influence schizophrenia.

Understanding the Social World

Each of us develops a **theory of mind**—a theory about other people's mental states (their beliefs, desires, feelings) that allows us to predict how they will react in a given situation. People with schizophrenia have difficulty with tasks that require an accurate theory of mind (Russell et al., 2006) and may thus find relating to others confusing. Because people with schizophrenia have difficulty interpreting emotional expression in others, they don't fully understand the messages people convey. The symptoms of paranoia and social withdrawal in people with schizophrenia may be a direct result of this social confusion (Frith, 1992). To a person with schizophrenia, other people can seem to behave in random and unpredictable ways. Thus, it makes sense that he or she tries to come up with an explanation for other people's

Theory of mind

People with schizophrenia may have difficulty accurately “reading” other people’s emotional expressions, which can make social interactions confusing and lead them to respond inappropriately.

behavior (a paranoid delusion) or else tries to minimize contact with others because their behavior seems inexplicable.

In spite of the fact that they basically were genetically identical, the Genain quads did not have the same level of social skills or ability to navigate the social world. For instance, Myra was able to work as a secretary for most of her life—a job that requires social awareness and social skills (Mirsky et al., 2000). She had markedly better social skills and stronger social desires than Hester—qualities that enabled her to have a boyfriend at school (Rosenthal, 1963).

Stressful Groups

Orphanages are notoriously stressful environments, which may be a major reason why being raised in an orphanage increases the likelihood of later developing schizophrenia in those who are genetically vulnerable. In fact, children born to a parent with schizophrenia are more likely to develop schizophrenia as adults if they were raised in an institution than if they were raised by the parent with schizophrenia. In addition, genetically vulnerable children raised by foster parents who do not have schizophrenia are even less likely to develop the disorder than are vulnerable children raised in an orphanage or raised by a parent with schizophrenia (Mednick et al., 1998). These findings suggest that, of the three types of environments in which an individual with a vulnerability to schizophrenia can grow up, a foster family is the least stressful.

Stress also contributes to whether someone who recovered from schizophrenia will relapse (Gottesman, 1991; Ventura et al., 1989). Almost two thirds of people hospitalized with schizophrenia live with their families after leaving the hospital. These families can create a stressful environment for a person with schizophrenia, especially if the family is high in expressed emotion. The concept of **high expressed emotion (high EE)** is not aptly named: It’s not just that the family with this characteristic expresses emotion in general, but rather that family members express critical and hostile emotions and are over-involved (for example, by frequently criticizing or nagging the patient to change his or her behavior; Wuerker et al., 2002). In fact, hospitalized patients who return to live with a family high in EE are more likely to have a relapse than patients who do not return to live with such a family (Butzlaff & Hooley, 1998; Kavanagh, 1992; Vaughn & Leff, 1976). However, note that high EE does not cause schizophrenia in the first place.

The Genain quads certainly experienced significant stress, and—as you can guess from what you’ve read so far—their family would be considered high in EE. Psychologist David Rosenthal (1963) reported that the quads’ father was particularly critical, almost constantly angry, and extremely controlling—in fact, so extreme was his need to control his children that he forbade his daughters to close any doors, even the one to the bathroom.

The relationship between high EE and relapse of schizophrenia is a correlation. Although it’s possible that the critical and controlling behaviors of family members, in part, cause a relapse, it is also equally possible that the causality goes the other way—that people whose symptoms of schizophrenia are more severe between episodes elicit

High expressed emotion (high EE)

A family interaction style characterized by hostility, unnecessary criticism, or emotional overinvolvement.

more attempts by their family members to try to minimize the psychotic, disorganized, or negative symptoms. And then these behaviors lead the family to be classified as high in EE. This explanation may apply, in part, to the Genain family: Among the four sisters, Hester's symptoms were the most chronic and debilitating. She received the most physical punishment, including being whipped and having her head dunked in water, often in response to behaviors that her father wanted her to stop.

Researchers have also discovered ethnic differences in how patients perceive critical and intrusive family behaviors. Among black American families, for instance, behaviors by family members that focus on problem solving are associated with a better outcome for the schizophrenic individual, perhaps because the behavior is interpreted as reflecting caring and concern (Rosenfarb, Bellack, & Aziz, 2006). Thus, what is important is not the family behavior *in and of itself*, but how such behavior is perceived and interpreted by family members.

Immigration

A well-replicated finding is that schizophrenia is more common among immigrants, compared both to people who stayed in the immigrants' original country and to people who are natives in the immigrants' adopted country (Cantor-Graae & Selten, 2005; Lundberg et al., 2007). This higher rate of schizophrenia among immigrants occurs among people who have left a wide range of countries and among people who find new homes in a range of European countries. In fact, one meta-analysis found that being an immigrant was the second largest risk factor for schizophrenia, after a family history of this disorder (Cantor-Graae & Selten, 2005). Both first-generation immigrants—that is, those who left their native country and moved to another country—and their children have relatively high rates of schizophrenia; this is especially true for immigrants and their children who have darker skin color than the natives of the adopted country, which is consistent with the role of social stressors (discrimination in particular) in schizophrenia (Selten, Cantor-Graae, & Kahn, 2007). For instance, the increased rate of schizophrenia among African-Caribbean immigrants to Britain (compared to British and Caribbean residents who are not immigrants) may arise from the stresses of immigration, socioeconomic disadvantage, and racism (Jarvis, 1998). Researchers have sought to rule out potential confounds such as illness or nutrition, but have yet to find such an explanation for the higher risk of schizophrenia among immigrants. Case 12.3 describes the symptoms of schizophrenia in an immigrant from Haiti to the United States.

CASE 12.3 ► FROM THE OUTSIDE: Schizophrenia

Within a year after immigrating to the United States, a 21-year-old Haitian woman was referred to a psychiatrist by her schoolteacher because of hallucinations and withdrawn behavior. The patient was fluent in English, although her first language was Creole. Her history revealed that she had seen an ear, nose, and throat specialist in Haiti after her family doctor could not find any medical pathology other than a mild sinus infection. No hearing problems were noted and no treatment was offered. Examination revealed extensive auditory hallucinations, flat affect, and peculiar delusional references to voodoo. The psychiatrist wondered if symptoms of hearing voices and references to voodoo could be explained by her Haitian background, although the negative symptoms seem unrelated. As a result, he consulted with a Creole-speaking, Haitian psychiatrist.

The Haitian psychiatrist interviewed the patient in English, French, and Creole. Communication was not a problem in any language. He discovered that in Haiti, the patient was considered “odd” by both peers and family, as she frequently talked to herself and did not work or participate in school activities. He felt that culture may have influenced the content of her hallucinations and delusions (i.e., references to voodoo) but that the bizarre content of the delusions, extensive hallucinations, and associated negative symptoms were consistent with the diagnosis of schizophrenia.

(Takeshita, 1997, pp. 124–125)

Spencer Platt/Getty Images

Schizophrenia occurs more frequently among immigrants (and their children) than among people who live in their native country. The various stresses of the immigration process, including financial problems and discrimination, are thought to account, at least in part, for this increased risk. The people in this photo are beginning the process of becoming legal immigrants.

In Case 12.3, notice that, although the women had odd and prodromal behaviors in Haiti, her full-blown symptoms did not emerge until she immigrated to the United States. Also notice that these symptoms could have emerged when she got older, even if she had stayed in Haiti. As compelling as single cases can be, full-scale studies—with adequate controls—must play a central role in helping us understand psychological disorders.

Economic Factors

Another social factor associated with schizophrenia is socioeconomic status: A disproportionately large number of people with schizophrenia live in urban areas and among lower economic classes (Hudson, 2005; Mortensen et al., 1999). As discussed in Chapter 2, researchers have offered two possible explanations for this association between the disorder and economic status: social selection and social causation (Dauncey et al., 1993). The **social selection** hypothesis proposes that those who are mentally ill “drift” to a lower socioeconomic level because of their impairments (and hence social selection is sometimes called *social drift*). Most vulnerable to social selection would be those whose illness prevents them from working or those who do not have—or do not make use of—family members who can care for them (Dohrenwend et al., 1992). Consider a young woman who grows up in a middle-class family and moves to a distant city after college, and where, after she graduates, she supports herself reasonably well working full time. She subsequently develops schizophrenia, but refuses to return home to her family, who cannot afford to send her much money. Her income now consists primarily of meager checks from governmental programs—barely enough to cover food and housing in a poor section of town where rent is cheapest. She has drifted from the middle class to a lower class.

Another explanation is **social causation**: The daily stressors of urban life, especially for the poor, trigger mental illness in those who are vulnerable (Freeman, 1994; Hudson, 2005). Social causation would explain cases of schizophrenia in people who grew up in a lower social class. The stressors these people experience include poverty or financial insecurity, as well as and living in neighborhoods with higher crime rates.

In a study designed to investigate the influence of social selection versus social causation, researchers in Ireland examined the relationship between social class at birth and later schizophrenia. These researchers found no differences in the rates of schizophrenia among the children of those in different social classes in Ireland (Mulvany et al., 2001). If social causation were at work, there should be more cases of schizophrenia among children born into lower social classes.

However, the data on this issue are not clear-cut. A similar study that included a more ethnically diverse sample in Israel found a higher rate of schizophrenia among those born into a lower social class, as would be predicted by social causation (Werner, Malaspina, & Rabinowitz, 2007). Note, however, that the social causation hypothesis focuses solely on social class. It does not address ethnicity or race, and so does not take into account the stressful effects of discrimination that arise for non-White immigrants.

Cultural Factors: Recovery in Different Countries

Although the prevalence of schizophrenia is remarkably similar across countries and cultures, the same cannot be said about recovery rates. Some studies report that people in developing countries have higher recovery rates than do people in industrialized countries (American Psychiatric Association, 2000; Kulhara & Chakrabarti, 2001), although this was not found in all earlier studies (Edgerton & Cohen, 1994; von Zerssen et al., 1990).

What accounts for this cultural difference? The important distinction may not be the level of industrial and technological development of a country, but how individualist its culture is. *Individualist cultures* stress values of individual autonomy and independence. In contrast, *collectivist cultures* emphasize the needs of the group, group cohesion, and interdependence. People with schizophrenia in collectivist cultures, such as those of Japan, Hong Kong, and Singapore, have a more favorable course and prognosis than people with schizophrenia in individualist cultures such as that of the United States (Lee et al., 1991; Ogawa et al., 1987; Tsoi & Wong, 1991).

Social selection

The hypothesis that those who are mentally ill “drift” to a lower socioeconomic level because of their impairments.

Social causation

The hypothesis that the daily stressors of urban life, especially as experienced by people in a lower socioeconomic level, trigger mental illness in those who are vulnerable.

The collectivist characteristics of a culture may help a patient to recover for several reasons. Consider that people in collectivist countries may:

1. be more tolerant of those with schizophrenia and therefore less likely to be critical, hostile, and controlling toward those individuals. That is, the families of patients with schizophrenia may be more likely to have lower levels of expressed emotion, decreasing the risk of relapse and leading to better recoveries (El-Islam, 1991).
2. elevate the importance of community and, in so doing, provide a social norm that creates more support for people with schizophrenia and their families.
3. have higher expectations of people with schizophrenia—believing that such individuals can play a functional role in society—and these expectations become a self-fulfilling prophecy (Mathews, Basily, & Mathews, 2006).

Thus, collectivism and strong family values may best explain the better recovery rates in less developed countries, which are generally more collectivist (Weisman, 1997). In such countries, to preserve family harmony, family members may be more tolerant of odd behaviors in a relative with schizophrenia, and they may be more willing to live with that person. In fact, for Latino patients, increasing their perception of the cohesiveness of the family (increased collectivism) is associated with fewer psychiatric symptoms and less distress (Weisman et al., 2005).

FEEDBACK LOOPS IN ACTION: Schizophrenia

No individual risk factor by itself accounts for a high percentage of the cases of schizophrenia. It is true that genetics, prenatal environmental events (such as maternal malnutrition and maternal illness), and birth complications affect fetal development (neurological factors) and can increase the likelihood that a person will develop schizophrenia. But many people who have these risk factors do not develop the disorder. Similarly, a dysfunctional family or another type of stressful environment (social factors) can contribute to, but do not cause, schizophrenia. And cognitive deficits (psychological factors) can contribute to the disorder because they create cognitive distortions but, again, such factors do not actually cause schizophrenia.

As usual, in determining the origins of psychopathology, no one factor reigns supreme in producing schizophrenia; instead, the feedback loops among the three types of factors provide the best explanation (Mednick et al., 1998; Tienari, Wahlberg, & Wynne, 2006). To get a more concrete sense of the effects of the feedback loops, consider the fact that economic factors (which are social) can influence whether a pregnant woman is likely to be malnourished, which in turn affects the developing fetus (and his or her brain). And various social factors create consistently high levels of stress among immigrants or among children raised in an orphanage. Thus, social events influence the degree of stress the individual experiences (a psychological factor), which can trigger factors that affect brain function, including increased cortisol levels. Coming full circle, these psychological and neurological factors are affected by culture (a social factor), which influences the prognosis, how people with schizophrenia are viewed, and how they come to view themselves (psychological factors).

Numerous studies have documented specific ways in which the three types of factors affect one another. For example, in one study (Tienari, Wahlberg, & Wynne, 2006), the researchers tracked adopted children over 21 years; some of them had biological mothers who had schizophrenia (genetic/neurological factor), others had biological mothers without schizophrenia. Some adoptive families exhibited a particular type of dysfunctional communication (social factor), in which the adoptive parent's way of communicating leaves the child puzzled and unsure what the parent means. This style of communication tends to be confusing and stressful to the children (neurological and psychological factors).

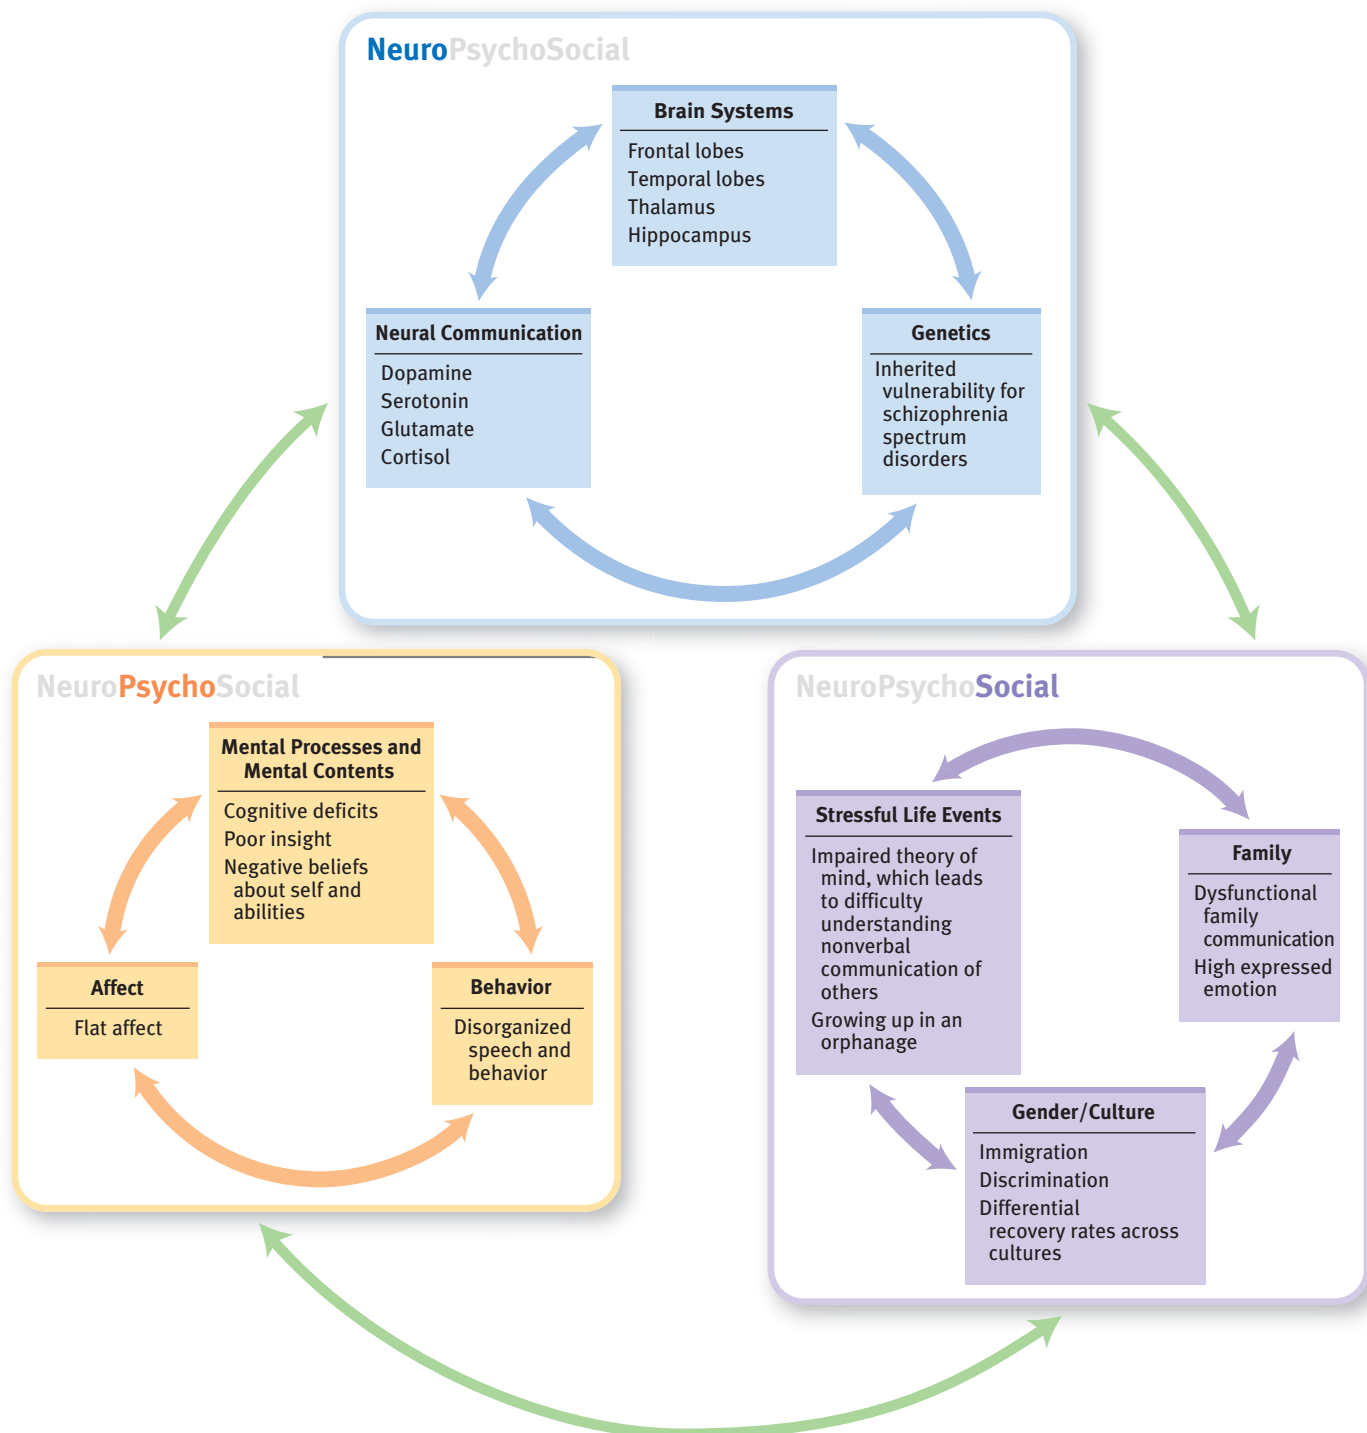

Among these adopted children, those with a low genetic risk of schizophrenia were unlikely to develop any schizophrenia spectrum disorder regardless of whether the adoptive parents' style of communication was healthy or dysfunctional. In contrast, the parents' style of communication made a big difference for those children

with a higher genetic risk—those whose mothers did have schizophrenia: Those raised in a stressful environment, with confusing and unpredictable communication from adoptive parents, were almost nine times more likely to develop the disorder than those who were raised by adoptive parents with a better communication style; the rates were 13% compared to 1.5% (Tienari, Wahlberg, & Wynne, 2006).

These interactions through feedback loops (see Figure 12.5) illustrate the diathesis–stress model. Researchers explain how stress can affect those who have

Figure 12.5

an underlying vulnerability to schizophrenia (Walker & Diforio, 1997). The key idea is that vulnerable people are biologically predisposed either to produce too much stress hormones or to be too sensitive to the effects of such hormones when they encounter a stressful event (van Os & Delespaul, 2003). The excess hormones or the excessive sensitivity to them can activate certain dopamine pathways too strongly, which then exacerbates schizophrenia symptoms. The social withdrawal common among people with schizophrenia may thus be an attempt to decrease stress (Walker & Diforio, 1997). Consistent with this view, people with schizophrenia who took part in a stress management program had fewer hospital admissions 1 year later (Norman et al., 2002). Moreover, as this model predicts, people with schizophrenia have higher baseline levels of cortisol, as do people at risk for schizophrenia. And antipsychotic medications lower the high cortisol levels in people with schizophrenia.

In addition, the neurocognitive deficits that accompany schizophrenia leave these patients with fewer cognitive resources to cope with stressful events. For example, their lack of insight and impaired theory of mind make it difficult for them to plan adequately. Cognitive deficits give rise to cognitive distortions, which can give rise to delusions that ultimately lead to social withdrawal (Beck & Rector, 2005). And the distorted ways of thinking about self and the world create stress, which produces higher levels of cortisol as a result of the hyperactivation of the hypothalamic-pituitary-adrenal (HPA) axis, which leads to a cascade of neurological events that further decreases cognitive functioning.

The Genain quads illustrate the effects of these feedback loops. A family history of schizophrenia as well as prenatal complications made the quads neurologically vulnerable to developing schizophrenia. They were socially isolated, were teased by other children, and experienced physical and emotional abuse. Had the Genain quads grown up in a different home environment, with parents who treated them differently, it is possible that some of them might not have developed schizophrenia and those who did might have suffered fewer relapses.

Key Concepts and Facts About Understanding Schizophrenia

- A variety of neurological factors are associated with schizophrenia:
 - Abnormalities in brain structure and function have been found in the frontal and temporal lobes, the thalamus, and the hippocampus. Moreover, certain brain areas do not appear to interact with each other properly. People with schizophrenia are more likely to have enlarged ventricles than are other people. The brain abnormalities give rise to biological markers in some individuals.
 - These brain abnormalities appear to be a result of, at least in some cases, maternal malnourishment or illness during pregnancy or to fetal oxygen deprivation.
 - Schizophrenia is associated with abnormalities in dopamine, serotonin, and glutamate activity, as well as a heightened stress response and increased cortisol production.
 - Less than 15% of people with schizophrenia have a first-degree relative (who is not a twin) who also has the disorder, but genetics is still the strongest predictor that a given individual will develop schizophrenia. Genetics alone, though, cannot explain why a given individual develops the disorder.
- Psychological factors that are associated with schizophrenia and shape the symptoms of the disorder include:
 - cognitive deficits in attention, memory, and executive functioning;
 - dysfunctional beliefs and attributions; and
 - difficulty recognizing and conveying emotions.
- Various social factors are also associated with schizophrenia:
 - an impaired theory of mind, which makes it difficult to understand other people's behavior, which in turn means that that other people's behavior routinely appears to be unpredictable;
 - a stressful home environment, such as being raised in an orphanage or by a parent with schizophrenia;
 - the stresses of immigration—particularly for people likely to encounter discrimination—and economic hardship; and
 - the individualist nature of the culture, which is associated with lower recovery rates for people with schizophrenia.

Treating Schizophrenia

The Genain sisters were treated at NIMH and then subsequently in hospitals, residential settings, and community mental health centers. During the early years of the quads' illness, antipsychotic medications were only just beginning to be used, and treatments that target psychological and social factors have changed substantially since then. Today, treatment for schizophrenia occurs in steps, with different symptoms and problems targeted in each step (Green, 2001).

STEP 1: When the patient is actively psychotic, first reduce the positive symptoms.

STEP 2: Reduce the negative symptoms.

STEP 3: Improve neurocognitive functioning.

STEP 4: Reduce the person's disability and increase his or her ability to function in the world.

As we'll see, the last step is the most challenging.

Targeting Neurological Factors in Treating Schizophrenia

At present, interventions targeting neurological factors generally focus on the first two steps of treatment: reducing positive symptoms and reducing negative symptoms. Some such treatments focus on the third step: improving cognitive function.

Medication

The first progress in using medication to treat symptoms of schizophrenia began in the 1950s, with the development of the first antipsychotic (also called *neuroleptic*) medication, *thorazine*. Since then, various antipsychotic medications have been developed, and two general types of these medications are now used widely, each with its own set of side effects. In this section we examine these medications and their side effects. We begin with the traditional antipsychotic medications, and discuss their potential drawbacks; we then consider the new generations of medications, and their benefits and drawbacks; following this, we examine what happens when people with schizophrenia stop taking their medication; finally, we consider whether it would be helpful to give medication to people with early signs of schizophrenia.

Traditional Antipsychotics

Thorazine (chlorpromazine) and other similar antipsychotics are dopamine antagonists, which effectively block the action of dopamine. Positive symptoms—hallucinations and delusions—diminish in approximately 75–80% of people with schizophrenia who take such antipsychotic medications (Green, 2001). Since their development, traditional antipsychotics have been the first step in treating schizophrenia. When taken regularly, they can reduce the risk of relapse: Only 25% of those who took antipsychotic medication for 1 year had a relapse, compared to 65–80% of those not on medication for a year (Rosenbaum et al., 2005). Traditional antipsychotics have sedating properties, which affect patients quickly; above and beyond such sedation, improvement in psychotic symptoms can take anywhere from 5 days to 6 weeks (Rosenbaum et al., 2005).

Some of the side effects of traditional antipsychotics create problems when a person takes them regularly for an extended period of time. Patients can develop **tardive dyskinesia**, an enduring side effect that produces involuntary lip smacking and odd facial contortions as well as other movement-related symptoms. Although tardive dyskinesia typically does not go away even when traditional antipsychotics are discontinued, its symptoms can be reduced with another type of medication. It is interesting to note, however, that decades before antipsychotic medications existed, clinicians described motor symptoms very similar to those of tardive dyskinesia in some patients who had what would now be labeled schizophrenia (Turner, 1989). This observation implies that it is possible that at least in some cases of tardive

Tardive dyskinesia

An enduring side effect of traditional antipsychotic medications that produces involuntary lip smacking and odd facial contortions as well as other movement-related symptoms.

dyskinesia are a by-product of schizophrenia itself, not a side effect of the medications. Other side effects of traditional antipsychotics include tremors, weight gain, and a sense of physical restlessness.

Atypical Antipsychotics: A New Generation

More recently, a different class of medications has become available for the treatment of schizophrenia: **atypical antipsychotics** (also referred to as *second-generation antipsychotics*), which affect dopamine and serotonin and do not affect the motor areas of the brain as much as traditional antipsychotics. Because of how they work, they do not pose a risk of tardive dyskinesia. Examples of atypical antipsychotics include *Risperdal* (risperidone), *Zyprexa* (olanzapine), and *Seroquel* (quetiapine). In contrast to typical antipsychotics, with long-term use these newer drugs appear to reduce both positive and negative symptoms (Corrigan et al., in press) and may reduce cognitive deficits (Geddes et al., 2000; Keefe, Bollini, & Silva, 1999; Keefe et al., 2006). However, the beneficial effects of atypical antipsychotics on cognitive functioning are less robust than was initially thought (Green, 2007; Keefe, Sweeney, et al., 2007), and some studies have found that traditional antipsychotics work as well as atypical antipsychotics for those patients who can tolerate the side effects (Kahn et al., 2008).

Nonetheless, atypical antipsychotics have several advantages over traditional antipsychotics: (1) As yet, they have not been found to lead to tardive dyskinesia; (2) they can reduce comorbid symptoms of anxiety and depression (Marder, Davis, & Chouinard, 1997); and, (3) they improve daily functioning (Keefe, Bilder, et al., 2007). Like traditional antipsychotics, they decrease the likelihood of relapse, at least for 1 year (which is the longest period studied; Csernansky, Mahmoud, & Brenner, 2002; Lauriello & Bustillo, 2001). However, the benefits of newer antipsychotics must be weighed against medical costs: Side effects include changes in metabolism that cause significant weight gain and increased risk of heart problems, and these side effects can become so severe or problematic that some people won't or shouldn't continue to use these medications (McEvoy et al., 2007).

In order to compare the effects and side effects of traditional and second-generation antipsychotic medications, NIMH funded the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) research program. This large-scale study examined 1,460 patients in 57 U.S. sites. This landmark study did not apply many of the exclusion criteria common to previous studies typically conducted by drug companies, and thus it included a more representative sample of participants. Moreover, the medication phase of CATIE was extended to 18 months. Analyzing the results of the study will take years, but the most striking result thus far is the high rate of patients who stopped taking the medication they were taking at the beginning of the study. More than two thirds of the participants stopped, either because the medication they were taking didn't sufficiently help reduce symptoms or because of the side effects. Disappointingly, continued use of second-generation antipsychotics was not significantly better overall, primarily because of their side effects (Lieberman et al., 2005). Among these newer antipsychotics, no particular medication stood out as superior (McEvoy et al., 2006; Tamminga, 2006).

This woman is exhibiting signs of tardive dyskinesia—involuntary lip smacking and odd facial grimaces that can be an enduring side effect of long-term use of traditional antipsychotic medication. Such side effects can persist even after the antipsychotic medication is discontinued. Symptoms of tardive dyskinesia can be reduced with other medications.

Atypical antipsychotics

A relatively new class of antipsychotic medications that affect dopamine and serotonin activity but create fewer movement-related side effects than do traditional antipsychotics; also referred to as *second-generation antipsychotics*.

Either type of antipsychotic medication is considered “successful” when it significantly reduces symptoms and the side effects can be tolerated. However, sometimes medication is not successful because it wasn’t really given a fighting chance: patients often stop taking their prescribed medication without consulting their doctor, which is referred to as *noncompliance*. As in the CATIE study, many people who stop taking their medication—whether in consultation with their doctor or not—cite significant unpleasant side effects as the main reason.

A unique study set out to investigate the side effects of antipsychotic medications in *healthy* participants, who took a single dose of each of the following, in random order: a traditional antipsychotic (haloperidol), an atypical antipsychotic (risperidone), and a placebo. Both types of antipsychotic medication caused some side effects that were similar to the negative symptoms of schizophrenia, particularly, but not limited to, *alogia*, which in this case was due to drowsiness (Artaloytia et al., 2006). Clearly, there is a need for medications that can reduce symptoms while not creating side effects that lead people to stop taking the drug.

Discontinuing Medication

Given how often patients stop taking their medication, we need to understand the effects of discontinuing medication. When people with schizophrenia discontinue their medication, they are more likely to relapse. One study found that among those who were stable for over 1 year and then stopped taking their medication, 78% had symptoms return within a year after that and 96% had symptoms return after 2 years (Gitlin et al., 2001). Various studies have found similar results (Cunningham et al., 2001; Perkins, 1999; Weiden & Zygmunt, 1997). And even up to 5 years after discharge, patients who had been hospitalized for schizophrenia and then discontinued their medication were five times as likely to relapse as those who didn’t (Robinson et al., 1999). With enough relapses, though, some people begin to understand the need for treatment:

I thought I could live my life without taking medication, but I ended up in the hospital again. Then it got worse. I started losing my concentration and my memory got bad. That’s when I finally realized I had to take medication.

(Miller & Mason, 2002, p. 25)

Preventive Medication?

Acute episodes of psychosis appear to create long-lasting disturbances in brain activation, cognitive functioning, and social relations. In addition, research suggests that pharmacological treatment administered soon after the first psychotic episode is associated with a better long-term prognosis, compared to treatment begun later (Harris et al., 2005; Marshall et al., 2005). Some clinicians and researchers are investigating whether early and aggressive use of antipsychotic medication can prevent or minimize the long-term damage that psychotic episodes appear to inflict (Lieberman, 1999). Moreover, as noted in Chapter 3, some researchers are exploring whether people who have prodromal symptoms of schizophrenia (but not enough symptoms to meet the diagnostic criteria for the disorder) can reduce the likelihood of a later psychotic episode by taking antipsychotic medication preemptively (McGorry & Edwards, 2002; McGorry et al., 2002). That is, researchers have asked whether preventive medication can help children and adolescents who have some symptoms but for whom the number and intensity of those symptoms do not meet the criteria for a psychotic disorder (Gosden, 2000; Gottesman & Erlenmeyer-Kimling, 2001; Warner, 2002).

Small pilot studies of early intervention with risperidone with at-risk groups have found some benefits, such as decreased positive symptoms (Cannon et al., 2002; Cornblatt, Lencz, & Obuchowski, 2002; McGorry et al., 2002; Wade et al., 2006). However, some researchers are concerned about whether adolescents or children, whose brains are still undergoing rapid development, should be given antipsychotic medications in the absence of a psychotic episode. All four of the Genain sisters were treated with medication; only Myra had long stretches of time when she did not need medication (Mirsky & Quinn, 1988). By 1995, Nora, Iris, and Hester were continuing

to take traditional antipsychotics; Myra was on a low dose of an atypical antipsychotic. These medications helped reduce their symptoms (Mirsky et al., 2000).

Brain Stimulation: ECT and TMS

Medication is not the only treatment that targets neurological factors. As mentioned in Chapter 1, electroconvulsive therapy (ECT) was originally used to treat schizophrenia, but generally was not successful. Although currently used only infrequently to treat this disorder, a course of ECT may be administered to people with active schizophrenia who are not helped by medications. ECT may reduce symptoms, but its effects are short-lived; furthermore, “maintenance” ECT—that is, regular although less frequent treatments—may be necessary for long-term improvement (Keuneman, Weerasundera, & Castle, 2002). Three of the Genain sisters—Nora, Iris, and Hester—received numerous sessions of ECT before antipsychotic medication was available. After ECT, their symptoms improved at least somewhat but, usually within months if not weeks, worsened again until the symptoms were so bad that a course of ECT was again administered (Mirsky et al., 1987; Rosenthal, 1963).

In experimental studies with small numbers of patients, transcranial magnetic stimulation (TMS) appears to decrease hallucinations, at least in the short term (Brunelin, Poulet, et al., 2006; d’Alfonso et al., 2002; Hoffman et al., 2000; Poulet et al., 2005). However, not all studies have found TMS to have this positive effect (McNamara et al., 2001; Saba et al., 2006). The specifics of ECT and TMS administration are discussed in Chapter 4.

Targeting Psychological Factors in Treating Schizophrenia

Treatments for schizophrenia that target psychological factors address the four general treatment steps; they (1) reduce psychotic symptoms through cognitive-behavior therapy (CBT); (2) reduce negative symptoms through CBT; (3) improve neurocognitive functioning through cognitive rehabilitation; and (4) improve overall functioning and quality of life through psychoeducation and motivational enhancement (Tarrier & Bobes, 2000).

Cognitive-Behavior Therapy

CBT addresses the patient’s symptoms and the distress that they cause. Treatment may initially focus on understanding and managing symptoms, by helping patients to:

- learn to distinguish hallucinatory voices from people actually speaking,
- highlight the importance of taking effective medications,
- discuss issues that interfere with compliance, and
- develop more effective coping strategies.

When a therapist uses CBT to address problems arising from delusions, he or she would not try to challenge the delusions themselves, but instead would try to help the patient move forward in life despite these beliefs. For instance, if someone believes that the CIA is after him, the CBT therapist might focus on the effects of that belief: What if the CIA were following him? How can he live his life more fully in spite this belief? Patient and therapist work together to implement new coping strategies and monitor medication compliance. In fact, such uses of CBT not only improve overall functioning (Step 4), but also can decrease positive symptoms (Step 1) (Bustillo et al., 2001; Pfammatter, Junghan, & Brenner, 2006; Rector & Beck, 2002a, 2002b) as well as negative symptoms (Step 2) (Dickerson, 2004; Tarrier et al., 2001; Turkington et al., 2006).

Cognitive Rehabilitation

Once psychotic symptoms have subsided, people with schizophrenia often continue to struggle with neurocognitive deficits that limit their ability to function. **Cognitive rehabilitation** (also called *neurocognitive remediation* or *cognitive mediation*)

Cognitive rehabilitation

A form of psychological treatment that is designed to strengthen cognitive abilities through extensive and focused practice; also called *neurocognitive remediation* or *cognitive mediation*.

is designed to strengthen cognitive abilities through extensive and focused practice (Wexler et al., 1997). Researchers have reported that such practice enhances the abilities to shift attention voluntarily, to sustain attention, and to reason, and increases mental flexibility (Krabbendam & Aleman, 2003; McGurk et al., 2007; Penadés et al., 2006; Wexler & Bell, 2005; Wykes et al., 2003). However, this treatment is expensive, and some studies find that its effects do not generalize beyond the specific tasks that are practiced (Silverstein et al., 2005). If in fact such practice does not generalize, then this treatment will have only minimal effects on the patient's functioning in the real world. Research efforts are under way to determine which specific rehabilitation techniques work to improve the general life skills of people with schizophrenia.

Treating Comorbid Substance Abuse: Motivational Enhancement

Because many people with schizophrenia also abuse drugs or alcohol, recent research has focused on developing treatments for people with both schizophrenia and substance-related disorders; motivational enhancement is one facet of such treatment. As we discussed in Chapter 9, patients who receive motivational enhancement therapy develop their own goals, and then clinicians help them meet those goals. For people who have both schizophrenia and substance-related disorders, one goal might be to take medication regularly (Lehman et al., 1998). For people who have two disorders, treatment that targets both of them appears to be more effective than treatment that targets one or the other alone (Barrowclough et al., 2001).

Targeting Social Factors in Treating Schizophrenia

Treatments that target social factors address three of the four general treatment steps: They identify early warning signs of positive and negative symptoms through family education and therapy; when necessary, such treatments involve hospitalizing people whose symptoms make them unable to care for themselves or whose symptoms put themselves or others at high risk of harm. These treatments also reduce certain negative symptoms through social skills training and improve overall functioning and quality of life through community-based interventions. Community-based interventions include work-related and residential programs (Tarrier & Bobes, 2000).

Family Education and Therapy

By the time a person is diagnosed with schizophrenia, family members typically have struggled for months—or even years—to understand and help their loved one. Psychoeducation for family members can provide practical information about the illness and its consequences, how to recognize early signs of relapse, how to recognize side effects of medications, and how to manage crises that may arise. Such education can decrease relapse rates (Pfammatter, Junghan, & Brenner, 2006; Pilling et al., 2002; Pitschel-Walz et al., 2001). In addition, family-based treatments may provide emotional support for family members (Dixon, Adams, & Luckstead, 2000). Moreover, family therapy, as noted in Chapter 4, can create more adaptive family interaction patterns:

In 1989, my older sister and I joined Mom in her attempts to learn more about managing symptoms of her illness. Mom's caseworkers met with us every 6 to 8 weeks for over 8 years. Mom, who had never been able to admit she had an illness, now told us that she did not want to die a psychotic. This was one of the many positive steps that we observed in her recovery. Over the years, other family members have joined our group. . . . With the help of the treatment team, we can now respond *effectively* to Mom's symptoms and identify stress-producing situations that, if left unaddressed, can lead to episodes of hospitalization. With Mom's help we have identified the different stages of her illness. In the first stage, we listed withdrawal, confusions, depression, and sleeping disorder. Fifteen years ago when mom reported her symptoms to me, I just told her everything would be okay. Today we respond immediately. For 8 years she has maintained a low dosage of medications, with increases during times of stress.

(Sundquist, 1999, p. 620)

Family therapy can also help high EE families change their pattern of interaction, so that family members are less critical of the patient, which can lower the relapse rate from 75% to 40% (Leff et al., 1990). However, as noted earlier in this chapter, not all families with high EE have such high relapse rates, especially in certain cultures (Cheng, 2002). Thus, treatment that changes a family's high EE pattern of interaction can help patients in some situations but is not always appropriate.

Group Therapy: Social Skills Training

Given the prominence of social deficits in many people with schizophrenia, clinicians often try to improve a patient's social skills. Social skills training usually occurs in a group setting, and its goals include learning to "read" other people's behaviors, learning what behaviors are expected in particular situations, and responding to others in a more adaptive way. Social skills training teaches these skills by breaking down complex social behaviors into their components: maintaining eye contact when speaking to others, taking turns speaking, learning to adjust how loudly or softly to speak in different situations, and learning how to behave when meeting someone new. The leader and members of a group take turns role playing these different elements of social interaction.

In contrast to techniques that focus specifically on behaviors, cognitive techniques focus on group members' irrational beliefs about themselves, their knowledge of social conventions, the beliefs that underlie their interactions with other people, and their ideas about what others may think; such beliefs often prevent people with schizophrenia from attempting to interact with others. These social skills may be applied to interactions with mental health professionals, such as discussing with a psychiatrist the side effects a medication is causing. Each element of the training is repeated several times, to help overcome patients' neurocognitive problems when learning new material. Research has shown that although social skills training does improve social skills and daily functioning that depends on social skills, it is less effective in preventing relapse or directly increasing employment (Bustillo et al., 2001; Kurtz & Mueser, 2008). Apparently such training is not sufficient to remove enough stress or reduce other contributing factors that may trigger a relapse.

Inpatient Treatment

Short-term or long-term hospitalization is sometimes necessary for people with schizophrenia. A short-term hospital stay may be required when someone is having an acute schizophrenic episode (is actively psychotic, extremely disorganized, or otherwise unable to care for himself or herself) or is suicidal or violent. The goal is to reduce symptoms and stabilize the patient. Inpatient treatment includes various therapy groups, such as a group to discuss medication side effects. Once the symptoms are reduced to the point where appropriate self-care is possible and the risk of harm is minimized, the patient will probably be discharged. Long-term hospitalization may occur only when other treatments have not significantly reduced symptoms and the patient needs full-time intensive care.

Legal measures have made it difficult to hospitalize people against their will (Torrey, 2001). Although these tougher standards protect people from being hospitalized simply because they do not conform to common social conventions (see Chapter 1), they also mean that people who have a disorder that *by its very nature* limits their ability to comprehend that they have an illness may not receive appropriate help until their symptoms have become so severe that normal functioning is impossible. Early intervention for ill adults who do not want help but do not realize that they are ill is legally almost impossible today. This issue will be discussed in more detail in Chapter 16.

Minimizing Hospitalizations: Community-Based Interventions

In Chapter 1 we noted that asylums and other forms of 24-hour care, treatment, and containment for those with severe mental illness have met with mixed success over the past several hundred years. Traditionally, people with chronic schizophrenia were likely to end up in such institutions. However, beginning in the 1960s with the widespread use of antipsychotic medications and building into the 1970s, the U.S. government

Deinstitutionalization was mandated without adequate funding for communities to take care of people with schizophrenia and other serious mental illnesses. One result has been increased poverty and homelessness among those with such disorders.

Community care

Programs that allow mental health care providers to visit patients in their homes at any time of the day or night; also known as *assertive community treatment*.

established the social policy of *deinstitutionalization*—trying to help those with severe mental illness live in their communities rather than remain in the hospital. Not everyone thinks that deinstitutionalization was a good idea, at least not in the way it has been implemented. The main problem is that the patients were sent out into communities without adequate social, medical, or financial support. It is now common in many U.S. cities to see such individuals on street corners, begging for money or loitering, with no obvious social safety net.

The good news is that some communities have adequately funded programs to help people with chronic schizophrenia and other chronic and debilitating psychological disorders live outside of institutions. **Community care** (also known as *assertive community treatment*) programs allow mental health staff to visit patients in their homes at any time of the day or night (Mueser et al., 1998; Stein & Test, 1980). Patients who receive such community care report greater satisfaction with their care; however, such treatment may not necessarily lead to better outcomes (Killaspy et al., 2006).

Residential Settings

Some people with schizophrenia may be well enough not to need hospitalization but are still sufficiently impaired that they cannot live independently or with family members. Alternative housing includes a range of supervised residential settings. At one extreme is highly supervised housing, in which a small number of people live with a staff member. Residents take turns shopping for and making meals. They also have household chores and attend house meetings to work out the normal annoyances of group living. Those able to handle somewhat more responsibility may live in an apartment building filled with people of similar abilities, with a staff member available to supervise any difficulties that arise. In independent living, in contrast, a staff member provides periodic home visits to patients living on their own. As patients improve, they transition to less supervised settings.

Vocational Rehabilitation

A variety of programs assist people with schizophrenia to acquire job skills; such programs are specifically aimed at helping patients who are relatively high-functioning but have residual symptoms that interfere with functioning at, or near, a normal level. Those who are more impaired may participate in *sheltered employment*, working in settings that are specifically designed for people with emotional or intellectual problems who cannot hold a regular job. Individuals in such programs may work in a hospital coffee shop or create craft items that are sold in shops. Those who are less impaired may be part of *supported employment* programs, which place individuals in regular work settings and provide an on-site job coach to help them adjust to the demands of the job itself and the social interactions involved in having a job (Bustillo et al., 2001). Examples of supported employment jobs might include work in a warehouse packaging items for shipment, or restocking items in an office or a store (“Project search,” 2006). What predicts how well a patient with schizophrenia can live and work in the world? Researchers have found that an individual’s ability to live and perhaps work outside of a hospital is associated with a specific cognitive function: his or her ability to use working memory (Dickinson & Coursey, 2002).

Details of the treatment that the Genain sisters received are only available for their time at NIMH, in the 1950s, when less was known about the disorder and how to treat it effectively. During the sisters’ stay at NIMH, therapists tried to reduce the parents’ level of emotional expressiveness and criticism; however, such attempts do not appear to have been effective. After their departure from NIMH, the sisters lived in a variety of settings: Nora lived first with Mrs. Genain, and subsequently in a supervised apartment with Hester. Iris was less able to live independently and lived in the hospital, in supervised residential settings, or at home with Mrs. Genain; she died in 2002. Myra, long divorced, generally lived independently; after Mrs. Genain died in 1983, Myra moved into her mother’s house with her older son. Like Iris, Hester spent many years in the hospital, then with Mrs. Genain. She lived with Nora in a supervised apartment until she died in 2003 (Mirsky & Quinn, 1988; Mirsky et al., 1987, 2000).

FEEDBACK LOOPS IN TREATMENT: Schizophrenia

To be effective, treatment for people with schizophrenia must employ interventions that induce interactions among neurological, psychological, and social factors (see Figure 12.6). When successful, medication (treatment targeting neurological factors) can reduce the positive and negative symptoms, and even help improve cognitive functioning. These changes in neurological and psychological factors, in turn, make it possible for social treatments, such as social skills training and vocational rehabilitation, to be more effective. If patients are not psychotic and have improved cognitive abilities, they can better learn social and vocational skills that allow them to function more effectively and independently.

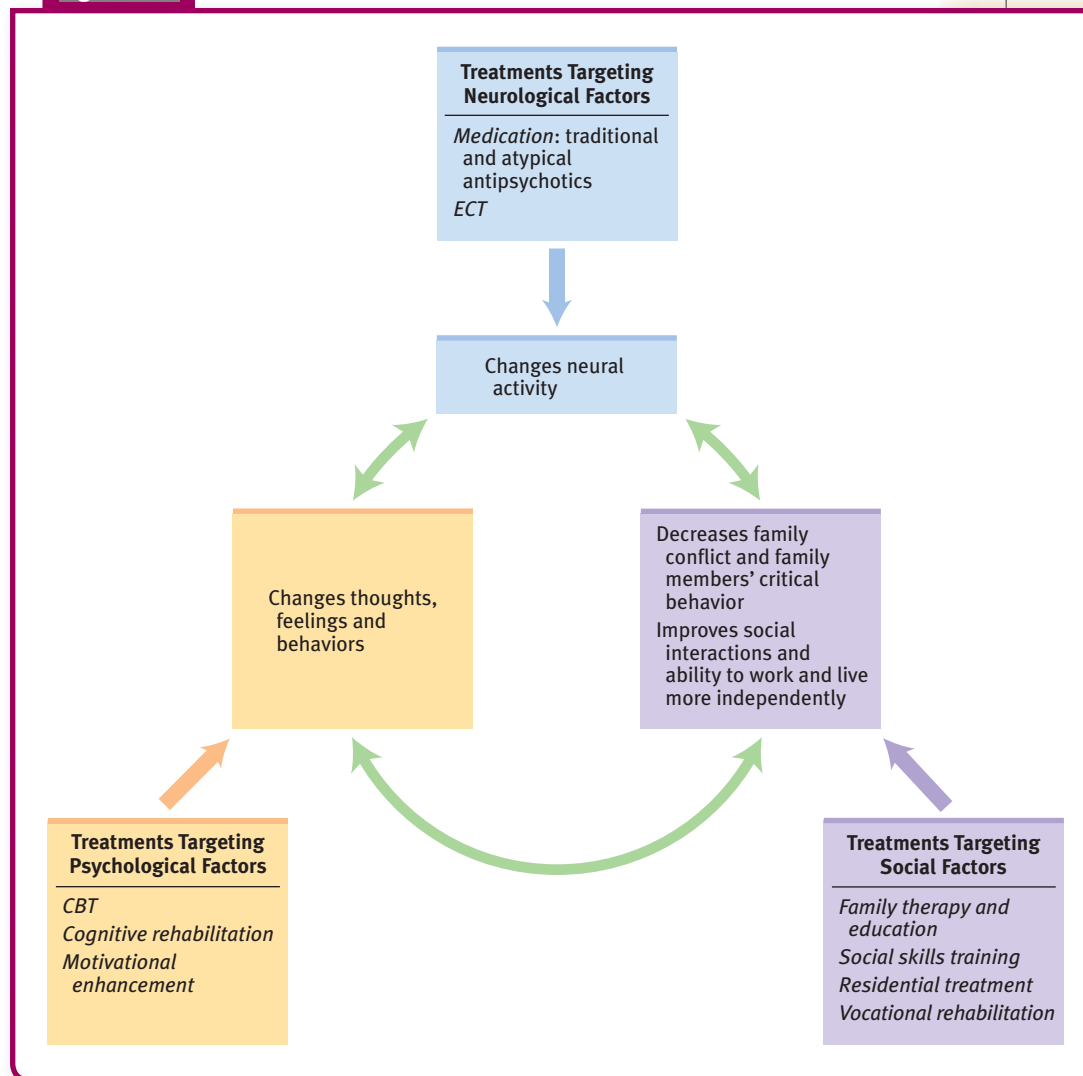

Figure 12.6

12.6 ▶ Feedback Loops in Treating Schizophrenia

Treatments that target psychological factors (CBT and cognitive rehabilitation) address steps 1, 3 and 4 of treatment: decreasing positive symptoms and cognitive deficits (psychological) and improving overall functioning and quality of life (social factor). Moreover, even when CBT may not *decrease* psychotic symptoms per se (step 1), it teaches patients how to function (step 4) despite these symptoms. In turn, as psychotic symptoms become more manageable, stress levels—and cortisol production—should decrease and thereby have fewer effects on brain functioning.

Similarly, treatments that target social factors, such as family therapy and psychoeducation, social skills groups, and vocational rehabilitation, also address

step 4: improving the patient's overall functioning and quality of life. As family and social interactions become less stressful, cortisol levels should decrease.

However, although medication can improve symptoms, it is not a panacea—in part because many patients stop taking it—which leaves an important role for psychosocial treatments. For instance, CBT (which addresses medication compliance and psychotic symptoms) focuses on motivation and beliefs, which are often not affected by medication. And treatments that target social factors (such as family therapy to change a high EE interaction pattern) can lower relapse rates (presumably via psychological and neurological factors associated with decreased stress). Therefore, each type of treatment for schizophrenia is a part of a larger whole.

Key Concepts and Facts About Treating Schizophrenia

- Treatments that target neurological factors include traditional and atypical antipsychotics; when these medications do not significantly decrease positive symptoms, ECT may be used. Although antipsychotic medications can decrease positive and, in some cases, negative symptoms, many patients discontinue such treatment because of side effects or because the medication did not help them enough. People who stop taking medication are much more likely to relapse.
- Treatments that target psychological factors include CBT to help patients better manage their psychotic symptoms, cognitive rehabilitation to reduce cognitive deficits, and motivational enhancement to decrease comorbid substance abuse.
- Treatments that target social factors include family education, family therapy to improve the interaction pattern among family members, and group therapy to improve social skills. Depending on the severity of an episode of schizophrenia, a patient may be treated in an inpatient facility or as an outpatient in the community. Community-based interventions include residential care and vocational rehabilitation.

SUMMING UP

Summary of What Are Schizophrenia and Other Psychotic Disorders?

According to DSM-IV-TR, schizophrenia is marked by two or more symptoms, at least one of which must be a positive symptom. These symptoms must be present for a minimum of 6 months and must significantly impair functioning. Research findings suggest that the disorganized symptoms form their own distinct cluster and should be grouped separately from delusions and hallucinations.

Research studies have indicated that cognitive deficits underlie negative and disorganized symptoms of schizophrenia. The DSM-IV-TR criteria have been criticized for omitting important cognitive and social deficits that lead to positive and negative symptoms and that are closely associated with prognosis.

DSM-IV-TR distinguishes five subtypes of schizophrenia: paranoid, disorganized, catatonic, undifferentiated, and residual schizophrenia. However, because the symptoms of schizophrenia often shift over time, an individual's subtype can change. Many researchers argue that a more useful way to distinguish subtypes of schizophrenia would be based on whether the individual has a deficit or nondeficit subtype.

Symptoms of schizophrenia can appear to overlap with those of other disorders, notably mood disorders and substance-related disorders. The category of psychotic disorders specifically requires symptoms of hallucinations or delusions; disorders in this category are schizophrenia, schizophreniform disorder, brief psychotic disorder, schizoaffective disorder, delusional disorder, and shared psychotic disorder. These disorders, along with schizotypal personality disorder, are part of a spectrum of schizophrenia-related disorders.

Most people with schizophrenia have at least one comorbid disorder. Men have an

earlier onset of the disorder than do women. Symptoms of the disorder typically evolve in phases: premorbid, prodromal, active, and then middle-to-late phases. People with this disorder who behave violently are most likely to have a comorbid disorder that is associated with violent behavior, such as a substance-related disorder. People with schizophrenia are more likely than other people to be victims of violence.

Thinking like a clinician

Suppose you are a mental health clinician working in a hospital emergency room in the summer; a woman is brought in for you to evaluate. She's wearing a winter coat, and in the waiting room, she talks—or shouts—to herself or an imaginary person. You think that she may be suffering from schizophrenia. What information would you need in order to make that diagnosis? What other psychological disorders could, with only brief observation, appear similar to schizophrenia?

Summary of Understanding Schizophrenia

A variety of neurological factors are associated with schizophrenia: (1) Abnormalities in brain structure and function have been found in the frontal and temporal lobes, the thalamus, and the hippocampus. Moreover, certain brain areas do not appear to interact with each other properly. People with schizophrenia are more likely to have enlarged ventricles than are other people. The brain abnormalities give rise to biological markers in some individuals. (2) These brain abnormalities appear to be a result of, at least in some cases, maternal malnourishment, illness during pregnancy, or fetal oxygen deprivation. (3) Schizophrenia is associated with abnormalities in dopamine, serotonin, and glutamate activity, as well as a heightened stress response and increased production of cortisol. (4) Genetics is the strongest predictor that a given individual will develop schizophrenia. Genetics alone, though, cannot explain why a given individual develops the disorder.

Psychological factors that are associated with schizophrenia and shape the symptoms of the disorder include: (1) cognitive deficits in attention, memory, and executive functioning; (2) dysfunctional beliefs and attributions; and (3) difficulty recognizing and conveying emotions.

Various social factors are also associated with schizophrenia: (1) an impaired theory of mind, which means that that other people's behavior routinely appears to be unpredictable; (2) a stressful home environment, such as being raised in an orphanage or by a parent with schizophrenia; (3) the stresses of immigration—particularly for people likely to encounter discrimination—and economic hardship; and (4) the individualist nature of the culture, which is associated with lower recovery rates for people with schizophrenia.

Thinking like a clinician

Using the neuropsychosocial approach, explain in detail how the three types of factors and their feedback loops may have led all four Genain sisters to develop schizophrenia.

Summary of Treating Schizophrenia

Treatments that target neurological factors include traditional and atypical antipsychotics; when these medications do not significantly decrease positive symptoms, ECT may be used. Although antipsychotic medications can decrease positive and, in some cases, negative symptoms, many patients discontinue such treatment because of side effects or because the medication did not help them enough. People who stop taking medication are much more likely to relapse.

Treatments that target psychological factors include CBT to help patients better manage their psychotic symptoms, cognitive rehabilitation to reduce cognitive deficits, and motivational enhancement to decrease comorbid substance abuse.

Treatments that target social factors include family education, family therapy to improve the interaction pattern among family members, and group therapy to improve social skills. Depending on the severity of an episode of schizophrenia, a patient may be treated in an inpatient facility or as an outpatient in the community. Community-based interventions include residential care and vocational rehabilitation.

Thinking like a clinician

Suppose you are designing a comprehensive treatment program for people with schizophrenia. Although you'd like to provide each program participant with many types of services, budgetary constraints mean that you have to limit the types of treatments your program offers. Based on what you have read about the treatment of schizophrenia, what would you definitely include in your treatment program, and why? Also list the types of treatment you'd like to include if you had a bigger budget.

Personality Disorders

Rachel Reiland wrote a memoir called *Get Me Out of Here*, about living with a personality disorder. In the opening of the book, Reiland remembers Cindy, the golden-haired grade-school classmate who was their teacher's favorite. At the end of a painting class, Cindy's painting was beautiful, with distinctive trees. Unfortunately, Rachel's painting looked like a "putrid blob." Rachel then recounts:

I seethed with jealousy as Mrs. Schwarzheuser showered Cindy with compliments. Suddenly, rage overwhelmed me. I seized a cup of brown paint and dumped half of it over my picture. Glaring at Cindy, I leaned across the table and dumped the other half over her drawing. I felt a surge of relief. Now Cindy's picture looked as awful as mine.

"Rachel!" Mrs. Schwarzheuser yelled. "You've completely destroyed Cindy's beautiful trees. Shame on you. You are a *horrible* little girl. The paint is everywhere—look at your jeans."

My blue jeans were soaked with brown paint. They looked ugly. I looked ugly. Mrs. Schwarzheuser frantically wiped up paint to keep it from dripping onto the floor. Everyone was watching.

I felt my body go numb. My legs, arms, and head were weightless. Floating. It was the same way I felt when Daddy pulled off his belt and snapped it. Anticipation of worse things to come—things I had brought on myself because I was different.

"In all my years, I've never seen a child like you. You are the *worst* little girl I've ever taught. Go sit in the corner, immediately."

Shame on Rachel. That language I understood. And deserved. . . .

Mrs. Schwarzheuser was right. I was horrible.

(2004, pp. 1–2)

Reiland's actions toward Cindy that day were troublesome and troubling, but many children have episodes of feeling intensely jealous and angry toward others and then act out those feelings. Such episodes don't necessarily indicate that a child, or the adult he or she grows up to be, has a disorder.

But some children and teenagers exhibit problems with relationships that persist into adulthood—problems that interfere with an aspect of daily life, such as work or family life. These problems have existed for so long that they seem to be a part of who the person is, a part of his or her personality. Such persistent problems indicate **personality disorders**, a category of psychological disorders characterized by a pattern of inflexible and maladaptive thoughts, feelings, and behaviors that arise across a range of situations and lead to distress or dysfunction.

Follow-up on Rachel Reiland

Personality disorders

A category of psychological disorders characterized by a pattern of inflexible and maladaptive thoughts, feelings, and behaviors that arise across a range of situations and lead to distress or dysfunction.

Diagnosing Personality Disorders

Unfortunately, Rachel Reiland's troublesome behavior continued as she grew older, at least when she was outside the house. Her teachers were frustrated with her, and angry at her; for instance, she vividly remembers when she was 12 years old, in her Catholic school, and sent, yet again, to the principal's office for breaking the rules:

"Miss Marsten [Reiland's maiden name]," Sister Luisa said disapprovingly. "I see you have managed to get yourself thrown out of the classroom again. What was it this time? A smart remark? Or just your usual disrespect?"

(Reiland, 2004, pp. 3–4)

It's not unusual for children to act out in school, as Reiland did. But as children get older, they mature. In Reiland's case, she went on to do well academically in high school and college, but in the nonacademic areas of her life things didn't go as well. While in high school, she developed anorexia nervosa. In high school and college, she frequently got drunk and was sexually promiscuous. She hadn't yet grown out of the maladaptive childhood patterns of behavior that got her into so much trouble with Sister Luisa.

In her mid-20s, Reiland unintentionally became pregnant when dating a man named Tim. They decided to marry and did so, even though she had a miscarriage before the wedding. They then had two children, first Jeffrey and 2 years later, Melissa. It seemed that Reiland had straightened out her life and that her childhood problems were behind her.

She temporarily stopped working while the children were young. When they were 2- and 4-years old, she found herself overwhelmed—alternately angry and needy. One day during this period of her life, her husband called to say he'd be late at work and wouldn't be home until 6 or 7 p.m. She responded by asking whether his coming home late was her fault. Reiland recounts their ensuing exchange:

"I didn't say it's your fault, honey. It's just that . . . well, I've got to get some stuff done." I began to twist the phone cord around my finger, tempted to wrap it around my neck.

"I'm a real pain in the ass, aren't I? You're pissed, aren't you?"

Tim tried to keep his patience, but I could still hear him sigh.

"Please, Rachel. I've got to make a living."

"Like I don't do anything around here? Is that it? Like I'm some kind of stupid housewife who doesn't do a god-damned thing? Is that what you're getting at?" Another sigh.

"Okay. Look, sweetheart, I've got to do this presentation this afternoon because it's too late to cancel. But I'll see if I can reschedule the annuity guy for tomorrow. I'll be home by four o'clock, and I'll help you clean up the house."

"No, no, no!"

I was beginning to cry.

"What now?"

"God, Tim. I'm such an idiot. Such a baby. I don't do a thing around this house, and here I am, wanting you to help me clean. I must make you sick."

"You don't make me sick, sweetheart. Okay? You don't. Look, I'm really sorry, but I've got to go."

The tears reached full strength. The cry became a moan that turned to piercing screams. *Why in the hell can't I control myself? The man has to make a living. He's such a good guy; he doesn't deserve me—no one should have to put up with me!*

"Rachel? Rachel? Please calm down. Please! Come on. You're gonna wake up the kids; the neighbors are gonna wonder what in the hell is going on. Rachel?"

"[Screw you!] Is that all you care about, what the *neighbors* think? [Screw] you, then. I don't need you home. I don't want you home. Let this [damn] house rot; let the [damn] kids starve. I don't give a shit. And I don't need your shit!"

(2004, pp. 11–12)

When Tim responds by saying he's going to cancel all his appointments and can be home in a few minutes, she sobs, "You must really hate me . . . you really hate me, don't you?" (Reiland, 2004, p. 12).

Personality

Enduring traits and characteristics that lead a person to behave in relatively predictable ways across a range of situations.

Reiland's behavior seems extreme, but is it so extreme that it indicates a personality disorder, or is it just an emotional outburst from a mother of young children who is feeling overwhelmed? In order to understand the nature of Reiland's problems and see how a clinician determines whether an individual's problems merit a diagnosis of personality disorder, we must focus on *personality*, and contrast normal versus abnormal variations of personality.

When you describe your roommate or new friends to your parents, you usually describe his or her **personality**—enduring traits and characteristics that lead a person to behave in relatively predictable ways across a range of situations. Similarly, when you imagine how family members will react to bad news you're going to tell them, you are probably basing your predictions of their reactions on your sense of their personality characteristics. Such characteristics—or *personality traits*—are generally thought of as being on a continuum, with a trait's name, such as “interpersonal warmth,” at one end of the continuum and its opposite, such as “standoffishness,” at other end of the continuum. Each person is unique in terms of the combination of his or her particular personality traits—and how those traits affect his or her behavior in various situations.

In this section we examine in more detail the DSM-IV-TR category of personality disorders and then the specific personality disorders that it contains.

What Are Personality Disorders?

Some people consistently and persistently exhibit extreme versions of personality traits, for example, being overly conscientious and rule-bound or, like Reiland, being overly emotional and quick to anger. Such extreme and inflexible traits that arise across a variety of situations can become maladaptive and cause distress or dysfunction—characteristics of a personality disorder. Let's examine the definition of personality disorders more closely.

As Table 13.1 notes, personality disorders reflect persistent thoughts, feelings, and behaviors that are significantly different from the norms in the individual's culture (Criterion A). Specifically, these differences involve the ABCs of psychological functioning:

- *affect*, which refers to the range, intensity, and changeability of emotions and emotional responsiveness and the ability to regulate emotions;
- *behavior*, which refers to the ability to control impulses and interactions with others; and
- *cognition (mental processes and mental contents)*, which refers to the perceptions and interpretations of events, other people, and oneself.

In addition, the differences in the ABCs of psychological functioning are relatively inflexible and persist across a range of situations (Criterion B in Table 13.1). Criterion B highlights how central these maladaptive personality traits are to the way the individual functions—the traits exert an influence in a wide variety of situations and the individual has extreme difficulty thinking, feeling, and behaving any differently. This rigidity across situations in turn leads to distress or impaired functioning, as it did for Sarah, in Case 13.1. To be diagnosed with a personality disorder, the maladaptive traits

Personality disorders are characterized by a pattern of inflexible and maladaptive thoughts, feelings, and behaviors that arise across a range of situations. This woman might be diagnosed with a personality disorder if she consistently got angry with little provocation and had difficulty controlling her anger in a variety of settings.

Table 13.1 ▶ DSM-IV-TR General Diagnostic Criteria for a Personality Disorder

- | |
|---|
| <p>A. An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two (or more) of the following areas:</p> <ol style="list-style-type: none"> (1) cognition (i.e., ways of perceiving and interpreting self, other people, and events) (2) affectivity (i.e., the range, intensity, lability, and appropriateness of emotional response) (3) interpersonal functioning (4) impulse control |
| <p>B. The enduring pattern is inflexible and pervasive across a broad range of personal and social situations.</p> |
| <p>C. The enduring pattern leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.</p> |
| <p>D. The pattern is stable and of long duration and its onset can be traced back at least to adolescence or early adulthood.</p> |
| <p>E. The enduring pattern is not better accounted for as a manifestation or consequence of another mental disorder.</p> |
| <p>F. The enduring pattern is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma).</p> |

typically should date back at least to early adulthood and should not primarily arise from a substance-related or medical disorder or another psychological disorder (American Psychiatric Association, 2000). We can now answer the question of whether Reiland's difficulties were more than those of an overwhelmed mother of young children. Specifically, her problems—in all four areas of functioning listed in Criterion A (cognition, affectivity, interpersonal functioning, and impulse control) as well as those listed in Criteria B through F—indicate that she has a personality disorder.

CASE 13.1 ► FROM THE OUTSIDE: Personality Disorder

Sarah, a 39-year-old single female, originally requested therapy at . . . an outpatient clinic, to help her deal with chronic depression and inability to maintain employment. She had been unemployed for over a year and had been surviving on her rapidly dwindling savings. She was becoming increasingly despondent and apprehensive about her future. She acknowledged during the intake interview that her attitude toward work was negative and that she had easily become bored and resentful in all of her previous jobs. She believed that she might somehow be conveying her negative work attitudes to prospective employers and that this was preventing them from hiring her. She also volunteered that she detested dealing with people in general. . . .

Sarah had a checkered employment history. She had been a journalist, a computer technician, a night watch person, and a receptionist. In all of these jobs she had experienced her supervisors as being overly critical and demanding, which she felt caused her to become resentful and inefficient. The end result was always her dismissal or her departure in anger. Sarah generally perceived her co-workers as being hostile, unfair, and rejecting. However, she would herself actively avoid them, complaining that they were being unreasonable and coercive when they tried to persuade her to join them for activities outside of work. For example, she would believe that she was being asked to go for drinks purely because her co-workers wanted her to get drunk and act foolishly. Sarah would eventually begin to take "mental health" days off from work simply to avoid her supervisors and colleagues.

(Thomas, 1994, p. 211)

Figure 13.1

13.1 ► Stability of Personality Disorders

Within 2 years of being diagnosed with a personality disorder, around one quarter to one third of the people in one study no longer met the diagnostic criteria for 12 consecutive months (Grilo et al., 2004). This finding indicates that personality disorders are not as stable as once thought.

Source: Grilo et al., 2004. For more information see the Permissions section.

Although personality disorders are generally considered to be stable, at least from adolescence into adulthood, research suggests that (as shown in Figure 13.1) these disorders are not as enduring as previously thought (Clark, 2009; Durbin & Klein, 2006; Lenzenweger, Johnson, & Willett, 2004; Zanarini et al., 2005); rather symptoms can improve over time for some people (Grilo et al., 2004; Johnson et al., 2000; Lenzenweger, 1999). Nevertheless, these disorders are typically among the most resistant to treatment.

As a group, people with personality disorders obtain less education (Torgersen, Kringlen, & Cramer, 2001) and are more likely never to have married or to be separated or divorced (Torgersen, 2005) than people who don't have such disorders. Personality disorders are associated with suicide: Among people who die by suicide, about 30% are thought to have had a personality disorder; among people who attempt suicide, about 40% are thought to have a personality disorder (American Psychiatric Association Work Group on Suicidal Behaviors, 2003).

Why Are Personality Disorders on Axis II Instead of Axis I?

When the five-axis diagnostic system of DSM was instituted, mental retardation and personality disorders were placed on Axis II because both involved persistent conditions that began in childhood and were believed to be stable—in contrast to the fluctuations observed with most Axis I disorders (Oldham, 2005). However, subsequent research indicates that personality disorders and Axis I disorders don't differ significantly on these two variables (Livesley, 2001). As discussed in previous chapters, many Axis I disorders involve symptoms that emerge in adolescence or young adulthood, or even in childhood (such as depression and eating disorders).

Moreover, as just noted, personality disorders can fluctuate over time. Thus, the reasons for putting personality disorders on a separate axis have not been borne out by research.

However, symptoms of personality disorders do contrast with those of Axis I disorders, in that they can be difficult to diagnose in a first interview, largely because patients may not be aware of the symptoms. In many cases, people who have a personality disorder are so familiar with their lifelong pattern of emotional responses, behavioral tendencies, and mental processes and contents that the ways in which this pattern is maladaptive may not be apparent to them. In fact, most people with a personality disorder identify *other* people or situations as being the problem, not something about themselves.

Assessing Personality Disorders

Given that many people with personality disorders are not aware of the nature of their problems, clinicians may diagnose a patient with a personality disorder based both on what the patient says and on patterns in the way he or she says it (Skodol, 2005). For instance, Sarah, in Case 13.1, probably had specific complaints about her co-workers, but the key information lies in the *pattern of her complaints*—in her claim that most of her co-workers, in various companies, were hostile and rejecting. More patient visits may be required to identify such a pattern and to diagnose a personality disorder than to diagnose an Axis I disorder. And more so than with other diagnoses, clinicians must make inferences about the patient in order to diagnose a personality disorder. However, clinicians must be careful not to assume that their inferences are correct without further corroboration; for example, a clinician should not assume that Sarah's problems with her co-workers were Sarah's fault without obtaining further information (Skodol, 2005).

To help assess personality disorders, clinicians and researchers may have patients complete personality inventories or questionnaires. To diagnose a personality disorder, the clinician may also talk with someone in the patient's life, such as a family member—who often describes the patient very differently than does the patient (Clark, 2007; Clifton, Turkehimer, & Oltmanns, 2004). The picture that emerges of someone with a personality disorder is a pattern of chronic *interpersonal* difficulties or chronic problems with *self*, such as a feeling of emptiness (Livesley, 2001).

According to DSM-IV-TR, when clinicians assess personality disorders, they should take into account the individual's culture, ethnicity, and social background. For instance, a woman who appears unable to make any decisions independently (even about what to make for dinner) and constantly defers to family members might have a personality disorder. However, for some immigrants, this pattern of behavior may be within a normal range for their ethnic or religious group. When immigrants have problems that are related to the challenges of adapting to a new culture or that involve behaviors or a worldview that is typical of people with their background, a personality disorder shouldn't be diagnosed. A clinician who isn't familiar with a patient's background should get more information from other sources. Sometimes it may not be obvious that a person is an immigrant, and sometimes the children of immigrants have incorporated a different set of social norms than those of the mainstream culture. If at all possible, clinicians should assess a patient's level of acculturation to determine whether he or she values and follows mainstream cultural norms—and if not, which norms he or she values and follows.

DSM-IV-TR Personality Clusters

DSM-IV-TR lists ten personality disorders, divided into three clusters. Each cluster of personality disorders shares a common

Although an individual may exhibit a pattern of problems that indicates a personality disorder, clinicians should take into consideration the individual's ethnicity, social background, and culture. If the individual's pattern of thoughts, feelings, and behaviors are characteristic of people from his or her background, a diagnosis of a personality disorder is not warranted.

Andrew Fox/Corbis

Table 13.2 ▶ DSM-IV-TR Personality Disorders, by Cluster

Cluster A involves odd or eccentric behaviors:	<p><i>Paranoid personality disorder</i> is characterized by mistrust and suspicion of others.</p> <p><i>Schizoid personality disorder</i> is characterized by few close relationships and a limited range of emotional expression.</p> <p><i>Schizotypal personality disorder</i> is characterized by few close relationships and eccentric perceptions, thoughts, and behaviors.</p>
Cluster B involves emotional, dramatic, or erratic behaviors:	<p><i>Antisocial personality disorder</i> is characterized by repeated violation of or disregard for the rights of others.</p> <p><i>Borderline personality disorder</i> is characterized by rapidly changing emotions, unstable relationships, and impulsivity.</p> <p><i>Histrionic personality disorder</i> is characterized by exaggerated emotions and excessive attention-seeking behaviors.</p> <p><i>Narcissistic personality disorder</i> is characterized by an excessive sense of self-importance and difficulty appreciating other people's perspectives.</p>
Cluster C involves anxious and fearful behaviors:	<p><i>Avoidant personality disorder</i> is characterized by a heightened sensitivity to rejection and social inhibition.</p> <p><i>Dependent personality disorder</i> is characterized by submissive, clingy behavior intended to elicit care from others, along with dependence on others for decision making and reassurance.</p> <p><i>Obsessive-compulsive personality disorder</i> is characterized by orderliness, perfectionism, and control at the expense of spontaneity and flexibility.</p>

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

feature (see Table 13.2). **Cluster A personality disorders** are characterized by odd or eccentric behaviors that have elements related to those of schizophrenia. **Cluster B personality disorders** are characterized by emotional, dramatic, or erratic behaviors that involve problems with emotional regulation. **Cluster C personality disorders** are characterized by anxious or fearful behaviors.

Table 13.3 provides an overview of facts about personality disorders in general. In the subsequent discussions of the individual personality disorders, you may notice that adding the prevalence rates for the various disorders gives a higher total than the overall prevalence rate of 14% listed in Table 13.3. This mathematical discrepancy is explained by the high comorbidity, also noted in the table: Half of people who have a personality disorder will be diagnosed with at least one other personality disorder (and in some cases, with more than one other personality disorder).

Criticisms of the DSM-IV-TR Category of Personality Disorders

The category of personality disorders, as defined in DSM-IV-TR, has been criticized on numerous grounds. One criticism is that DSM-IV-TR treats personality disorders as categorically distinct from normal personality (Livesley, 2001; Saulsman & Page, 2004; Widiger & Costa, 2002; Widiger & Lowe, 2008; Widiger & Trull, 2007). In contrast, most psychological researchers currently view normal personality and personality disorders as being on continua. In DSM-IV-TR terms, two people might differ only slightly in the degree to which they exhibit a personality trait, but one person would be considered to have a personality disorder and the other person would not. A related criticism is that the DSM-IV-TR criteria for personality disorders create an arbitrary cutoff on the continuum between normal and abnormal (Livesley, 2001; Widiger & Trull, 2007).

Another criticism pertains to the clusters, which were organized by superficial commonalities. Research does not necessarily support the organization of personality disorders into these clusters (Blais et al., 1997; Sheets & Craighead, 2007). Moreover, the specific personality disorders are not clearly distinct from each other

Cluster A personality disorders

Personality disorders characterized by odd or eccentric behaviors that have elements related to those of schizophrenia.

Cluster B personality disorders

Personality disorders characterized by emotional, dramatic, or erratic behaviors that involve problems with emotional regulation.

Cluster C personality disorders

Personality disorders characterized by anxious or fearful behaviors.

Table 13.3 ▶ An Overview: Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> • Researchers estimate that up to 14% of Americans will have at least one personality disorder over the course of their lives (Grant, Hasin, et al., 2004; Lenzenweger, 2006; Samuels et al., 2002; Torgersen et al., 2001).
Comorbidity
<ul style="list-style-type: none"> • Up to 75% of those with a personality disorder will also be diagnosed with an Axis I disorder (Dolan-Sewell, Krueger, & Shea, 2001; Lenzenweger, 2006). • Common comorbid disorders from Axis I are mood disorders, anxiety disorders, and substance-related disorders (Grant, Stinson, et al., 2004; Johnson, Cohen, Kasen, & Brook, 2006a; Lenzenweger, 2006). • Around 50% of people with a personality disorder will be diagnosed with at least one other personality disorder (Skodol, 2005).
Onset
<ul style="list-style-type: none"> • The DSM-IV-TR diagnostic criteria require that symptoms arise by young adulthood. • For one personality disorder—antisocial personality disorder—a diagnostic criterion requires that symptoms arise before age 15.
Course
<ul style="list-style-type: none"> • Symptoms of personality disorders are often relatively stable, but they may fluctuate or improve as people go through adulthood.
Gender Differences
<ul style="list-style-type: none"> • Specific personality disorders have gender differences in prevalence, but there is no such difference across all personality disorders.
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

(Blais & Norman, 1997; Kupfer, First, & Regier, 2002). For instance, schizoid and schizotypal personality disorders share a number of features, including a pattern of poor social skills and abilities and a small number of social contacts. Similarly, histrionic and narcissistic personality disorders share a pattern of grandiosity and the desire to be the center of attention.

In addition, some personality disorders are not clearly distinct from related Axis I disorders (Widiger & Trull, 2007). The diagnostic criteria for avoidant personality disorder, for example, overlap considerably with those for social phobia, as we'll discuss in detail in the section on avoidant personality disorder. Similarly, critics point out that the general criteria for personality disorders (Table 13.1, Criteria A through D) could apply to some Axis I disorders such as dysthymia and schizophrenia (Oldham, 2005).

The process by which the DSM-IV-TR criteria were determined is another target of criticism. The minimum number of symptoms needed to make a diagnosis, as well as the specific criteria, aren't necessarily supported by research results (Widiger & Trull, 2007). Moreover, different personality disorders require different numbers of symptoms and different levels of impairment (Livesley, 2001; Skodol, 2005; Tyrer & Johnson, 1996; Westen & Shedler, 2000).

The high comorbidity among personality disorders invites another criticism: that the specific personality disorders do not capture the appropriate underlying problems, and so clinicians must use more than one diagnosis to describe the types of problems exhibited by patients (Widiger & Mullins-Sweatt, 2005). In fact, the most frequently diagnosed personality disorder is *personality disorder not otherwise specified*, which is often diagnosed along with an additional personality disorder (Verheul, Bartak, & Widiger, 2007; Verheul & Widiger, 2004). As with other categories of disorders, the *not otherwise specified* diagnosis is used when a patient's symptoms cause distress or impair functioning but do not fit the criteria for any of the disorders within the relevant category—in this case, one of the ten specific personality disorders.

Understanding Personality Disorders in General

At one point, Reiland became impatient with her 4-year-old son Jeffrey and “lost it.” She slapped, then cursed him. As he cried, she commanded him to stop crying. He didn’t, and she proceeded to spank him so hard that it hurt her hand.

He had stopped crying, his fright overcoming his need to express his emotions. But his eyes were wide open, as big as I’d ever seen them. And absolutely, unequivocally horrified. That look stopped me.

The familiar feeling of weightlessness overtook me again. I knew Jeffrey’s look. I knew that feeling.

It had been a common part of my childhood—enduring rages that began and ended just as unpredictably. The reality slowly sunk in. I had beaten my child. Just as my father had beaten his. Just as I swore I never ever would. A wave of nausea rose within me. *I was just like my father.* Even my children would be better off without me. There was no longer any reason to stay alive.

(Reiland, 2004, p. 19)

Reiland’s realization was relatively unusual for someone with a personality disorder: She recognized in this instance that it was *she* who created a problem—*she* who had done something wrong, although her father never recognized his responsibility. He too was quick to anger and hit her and her siblings. Do personality disorders run in families? If so, to what extent do genes and environment lead to personality disorders? How might personality disorders arise?

Neurological Factors in Personality Disorders: Genes and Temperament

Perhaps the most influential neurological factor associated with personality disorders is genes (Cloninger, 2005; Paris, 2005). Researchers have not produced evidence that genes underlie specific personality disorders, but they have shown that genes clearly influence *temperament*, which is the aspect of personality that reflects a person’s typical affective state and emotional reactivity (see Chapter 2). Temperament, in turn, plays a major role in personality disorders. Genes influence temperament via their effects on brain structure and function, including neurotransmitter activity.

It is possible that the genes that affect personality traits can predispose some people to develop a personality disorder. For instance, some people are genetically predisposed to seek out novel and exciting stimuli, such as those associated with stock trading, race car driving, or bungee jumping, whereas other people are predisposed to become easily overstimulated and habitually prefer low-key, quiet activities, such as reading, writing, or walking in the woods. Such differences in temperament are the foundation on which different personality traits are built—and, at their extremes, temperaments can give rise to inflexible personality traits that are associated with personality disorders. Examples include a novelty seeker (temperament) who compulsively seeks out ever more exciting activities (inflexible behavior pattern), regardless of the consequences, and a person who avoids overstimulation (temperament) and turns down promotions because the new position would require too many activities that would be overstimulating (inflexible behavior pattern).

Reiland may well have inherited a tendency to develop certain aspects of temperament, which increased the likelihood of her behaving like her father in certain types of situations. However, her genes and her temperament don’t paint the whole picture; psychological and social factors also influenced how she thought, felt, and behaved.

Psychological Factors in Personality Disorders: Temperament and the Consequences of Behavior

Two psychological factors significantly contribute to personality disorders: temperament and operant conditioning. Although influenced by genes, temperament is also shaped by the environment—and ultimately is best conceptualized as a psychological factor. As just noted, temperament influences the types of situations to which individuals are likely to gravitate and to avoid—and how they are likely to behave

in those situations. The consequences of their behaviors (operant conditioning) will influence the likelihood that they will repeat the behaviors. Furthermore, the consequences can lead to pervasive dysfunctional beliefs—which can form the foundation for some types of personality disorders.

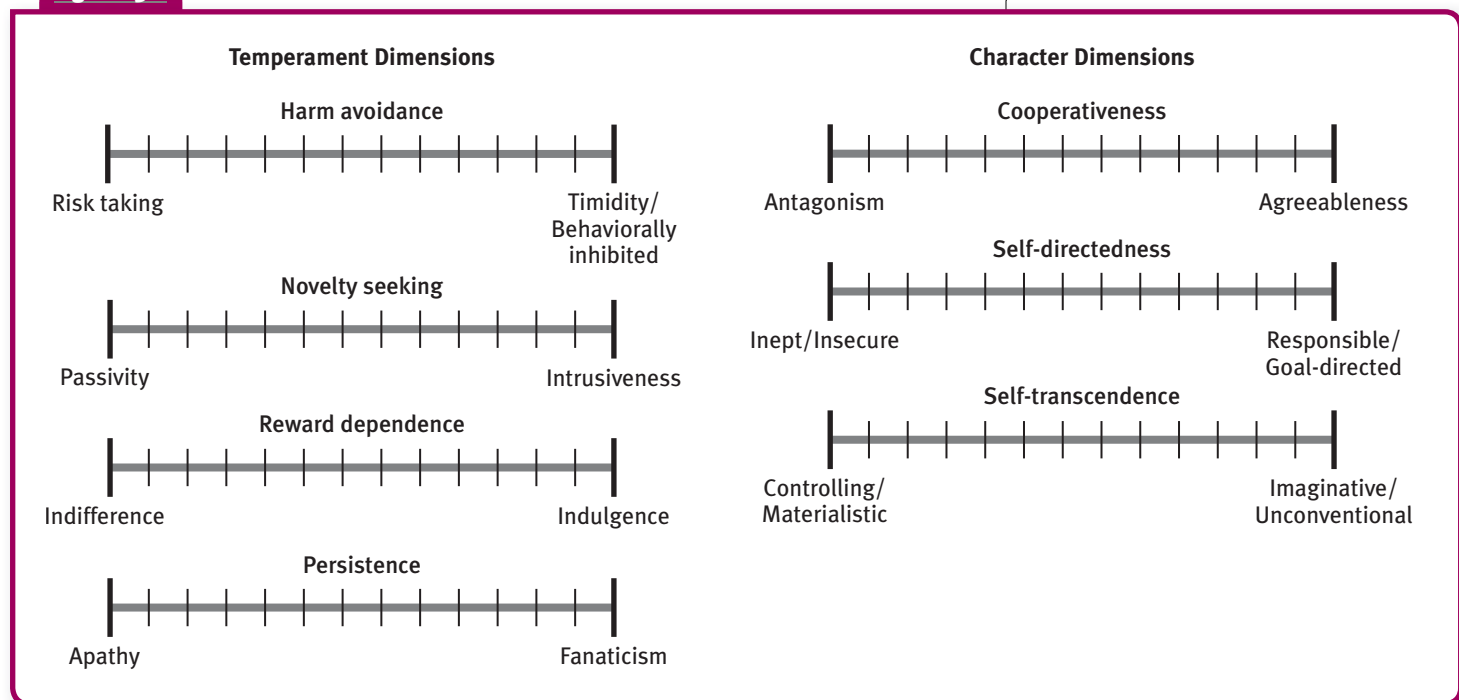

The Role of Temperament

Temperaments—and their contribution to personality disorders—can be classified in two different ways. As discussed in Chapter 2, Cloninger (1987) proposed four basic dimensions on which temperaments vary (see Figure 13.2; left side). The strength of each dimension varies across individuals, and each cluster of personality disorders is characterized by an extreme on a particular dimension.

In particular, people with Cluster A (odd/eccentric) personality disorders are not strongly motivated by relationships with other people—they avoid social risk taking and are generally indifferent to normal social rewards, such as attention from others. They tend to score low on reward dependence. Indeed, it's not just that being with other people isn't rewarding and doesn't motivate their behavior; rather, such people have the opposite motivation, preferring to be alone. People with Cluster B (dramatic/erratic) personality disorders tend to score high on novelty seeking and tend to engage in new, highly stimulating, or intensely demanding activities, perhaps leading them to get into arguments more frequently. People with Cluster C (fearful/anxious) personality disorders tend to be high on harm avoidance; they have in common a fear of uncertainty that leads them to withdraw from relationships, situations, or activities that most other people view as relatively safe. For instance, Sarah, in Case 13.1, generally perceived her co-workers as threatening and tried to avoid them.

Cloninger also proposed three character dimensions (see Figure 13.2; right side), which can help illuminate the nature of personality disorders; most personality disorders are marked by low levels of *cooperativeness*, *self-directedness*, and *self-transcendence*, which translate behaviorally into personality characteristics of being uncooperative, having difficulty regulating and adapting behavior, and being

Figure 13.2

13.2 ► Cloninger's Four Basic Temperaments and Three Character Dimensions Personality disorders are characterized by extremes on dimensions of temperament and character.

controlling. Each particular personality disorder within a cluster is associated with a combination of the temperament and character dimensions. For example, borderline personality disorder—characterized by emotional dysregulation and impulsivity—involves high levels of novelty seeking and reward dependence as well as low scores on the three character dimensions (Cloninger, 2005).

A second way to classify how temperaments relate to personality disorders is to group them according to the most basic characteristics that underlie the disorders. Mathematical techniques allow researchers to discover dimensions that cut across a set of measurements, which can reveal such underlying characteristics. Research that uses these techniques consistently yields four basic dimensions that are related to personality disorders (Mulder & Joyce, 1997; Trull & Durrett, 2005):

- *emotional dysregulation*, rapidly changing moods and irritability;
- *dissocial behavior (or psychopathy)*, a lack of moral conscience and an ability to manipulate others;
- *inhibitedness (or social withdrawal)*, a desire to avoid social interactions; and
- *compulsivity*, an overly developed sense of conscientiousness.

These four dimensions are heritable (Livesley, Jang, & Vernon, 1998).

The Consequences of Behavior

Although an infant may be born with a bias to develop certain temperamental characteristics, these characteristics—and personality traits—evolve through experience in interacting with the world. Personality traits involve sets of learned behaviors and emotional reactions to specific stimuli; what is learned is in part shaped by the consequences of behavior, including how other people respond to the behavior. The mechanisms of operant conditioning are at work whenever an individual experiences consequences of behaving in a certain way: If the consequences are positive, the behavior is reinforced (and hence likely to recur); if the consequences are negative, the behavior is punished (and hence likely to be dampened down).

The consequences of behaving in a specific way not only affect how temperament develops but also influence a person's expectations, views of others, and views of self (Bandura, 1986; Farmer & Nelson-Gray, 2005). Based on what they have learned, people can develop maladaptive and faulty beliefs, which in turn lead them to misinterpret other people's words and actions. These (mis)interpretations reinforce their views of themselves and the world in a pervasive self-fulfilling cycle, biasing what they pay attention to and remember, which in turn reinforces their views of self and others (Beck, Freeman, & Davis, 2004; Linehan, 1993; Pretzer & Beck, 2005; Young, 1990). For instance, at one point Rachel Reiland states her belief that her husband “doesn't deserve me—no one should have to put up with me!” (Reiland, 2004, p. 11). This belief leads her to be hypervigilant for any annoyance expressed or implied by her husband. She's likely to misinterpret his actions and comments as confirming her belief that she is undeserving, and she then alternates lashing out in anger with groveling in grief.

According to Aaron Beck and colleagues (2001, 2004), such pervasive and self-fulfilling dysfunctional beliefs are at the core of personality disorders. Such beliefs have three elements, and each personality disorder has its unique set of these elements:

1. automatic thoughts (e.g., “No one should have to put up with me because I'm so bad”);
2. interpersonal strategies (e.g., “If I grovel or cry, maybe he'll forgive me”); and
3. cognitive distortions (e.g., “He says he has to make a living—what he really means is that he thinks I'm not doing enough”) (Pretzer & Beck, 2005).

Social Factors in Personality Disorders: Insecurely Attached

Another factor that influences whether a person will develop a personality disorder is *attachment style*—the child's emotional bond and way of interacting with (and thinking about) his or her primary caretaker (Bowlby, 1969; see Chapter 1).

The attachment style established during childhood often continues into adulthood, affecting how the individual relates to others (Waller & Shaver, 1994). Most children develop a *secure attachment* (Schmitt et al., 2004), which is marked by a positive view of their own worth and of the availability of others. However, a significant minority of children develop an *insecure attachment*, which can involve a negative view of their own worth, the expectation that others will be unavailable, or both (Bretherton, 1991). People with personality disorders are more likely to have insecure attachment (Crawford et al., 2006).

People can develop insecure attachments for a variety of reasons, such as childhood abuse (sexual, physical, or verbal), neglect, or inconsistent discipline (Johnson, Bromley, & McGeoch, 2005; Johnson, Cohen, Chen, et al., 2006; Paris, 2001). Consider Reiland's experience with her father:

My father hadn't spared me because I was Daddy's little girl. It was because he worked such long hours and because I had witnessed so much I had become adept at avoiding him. Often his explosive violence had been irrational and triggered by the slightest provocation; a facial expression he found disrespectful, tears he didn't want to see, any expression of emotion he didn't have patience for. And the rules changed all the time. Something that could bring him to smile or laugh one day could provoke him to angrily pull off his belt a few days or hours later. . . . Dad had been far harsher on his daughters than his sons, particularly verbally. To a man who coveted control and saw any emotion, particularly tears, as weakness, his daughters could provoke the worst in him. In his mind, women were weak, manipulative, overemotional, and inferior.

(2004, p. 84)

Reiland's father abused her physically and verbally, alternating the abuse with bouts of neglect. However, such social risk factors may lead to psychopathology in general, not personality disorders in particular (Kendler et al., 2000). A single traumatic event does not generally lead to a personality disorder (Rutter, 1999).

FEEDBACK LOOPS IN ACTION: Understanding Personality Disorders

Neurological, psychological, and social factors create feedback loops with each other (see Figure 13.3). As with other kinds of psychological disorders, no one factor reigns supreme as the underlying basis of personality disorders. People must have several adverse factors—whether neurological, psychological, or social—to develop a personality disorder, and social adversity will have the biggest effect on those who are neurologically vulnerable (Paris, 2005). Careful examination of social risk factors, for instance, shows the importance of their influence on other factors: People with personality disorders tend to have parents with Axis I or II disorders (Bandelow et al., 2005; Siever & Davis, 1991). In Reiland's case, her father's unpredictable rages suggest some type of disorder, and neither parent functioned very well at home. Parents' dysfunctional behavior clearly creates a stressful social environment for children, and the children may also inherit a predisposition toward a specific temperament (neurological factor). Similarly, chronic stress and abuse, such as Reiland experienced, affects brain structure and function (neurological factor; Teicher et al., 2003), which in turn affects mental processes (psychological factor).

The specific personality disorder an individual develops depends on his or her temperament and family members' reactions to that temperament (Linehan, 1993; Rutter & Maughan, 1997). For instance, children with difficult temperaments—particularly behaviorally inhibited or passive temperaments—tend to have more conflict with their parents and peers (Millon, 1981; Rutter & Quinton, 1984), which leads them to experience a higher incidence of physical abuse and social rejection. These children may then come to expect (psychological factor) to be treated poorly by others (social factor). Thus, social factors can amplify underlying temperaments

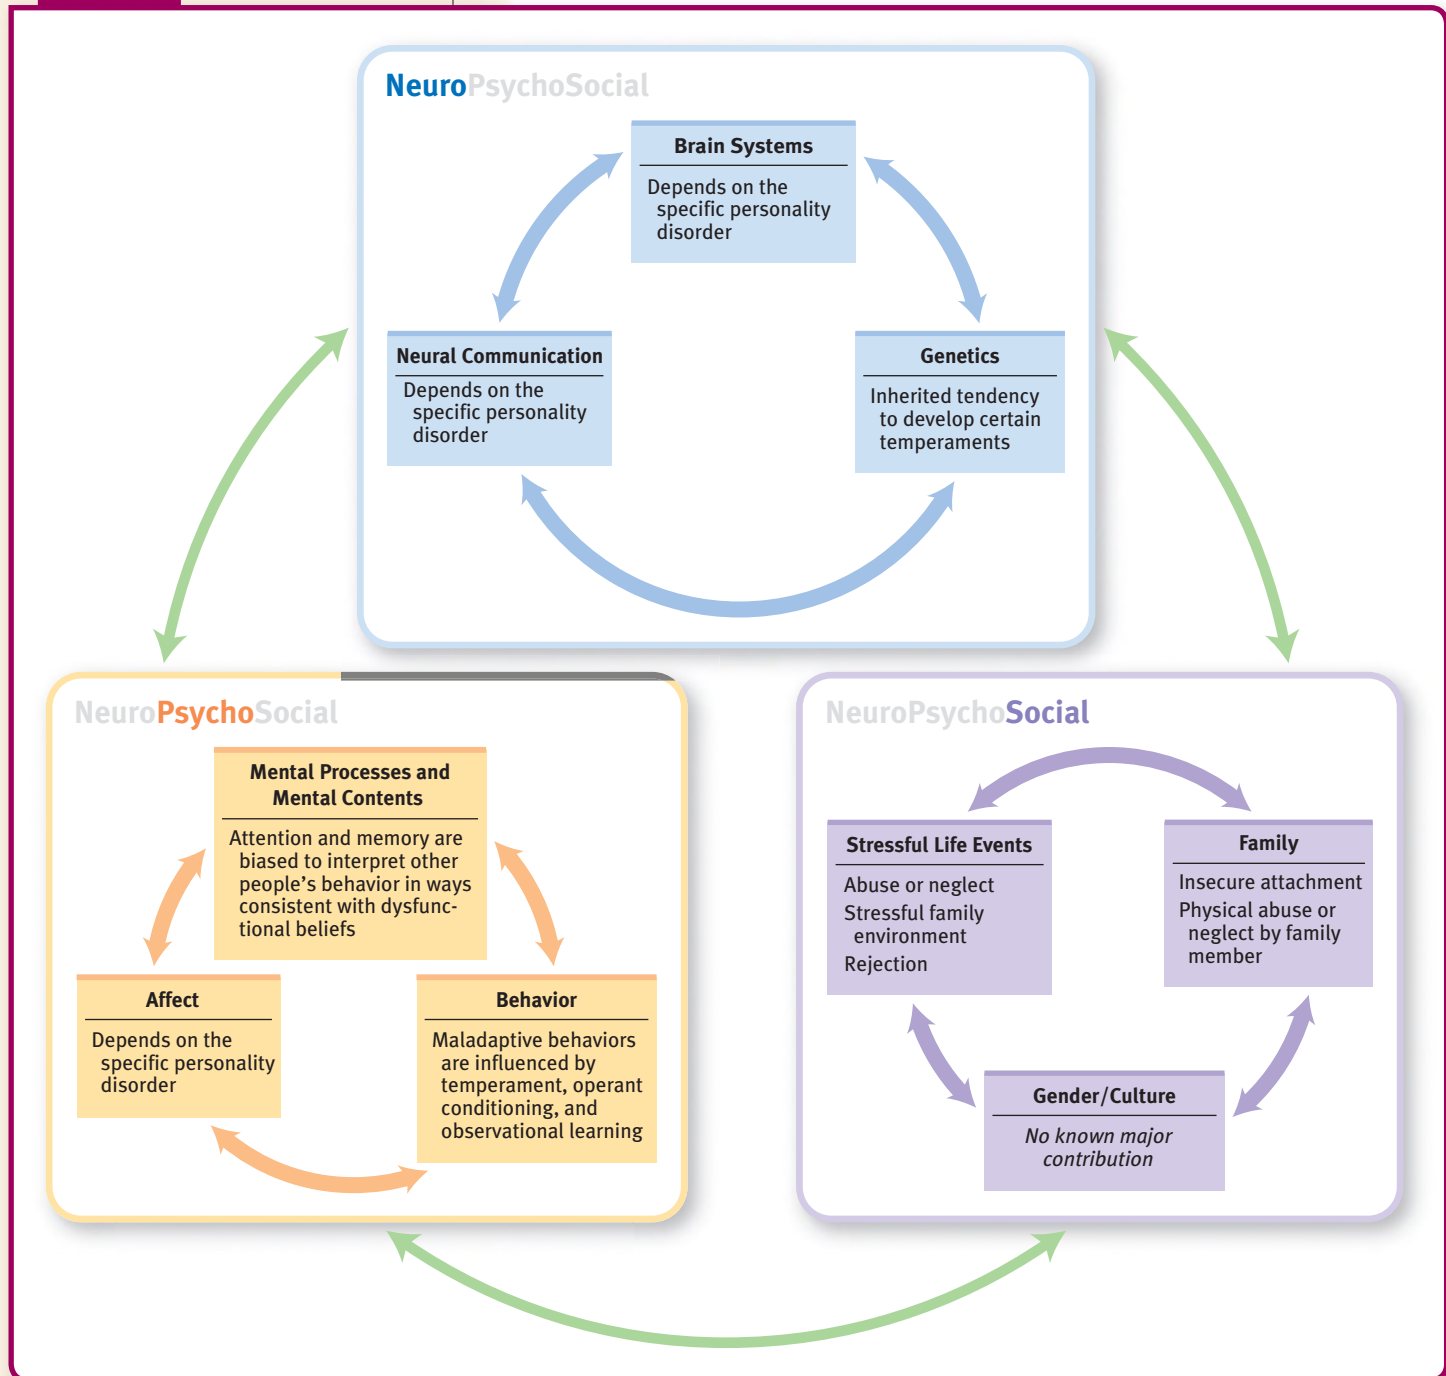

plainpicture

Insecure attachment to a parent can make a child vulnerable to developing a personality disorder. Insecure attachment can arise from abuse, neglect, or inconsistent discipline.

Figure 13.3

13.3 ► Feedback Loops in Action: Personality Disorders

and traits so that they subsequently form the foundation for a personality disorder (Caspi et al., 2002; Paris, 1996, 2005).

We earlier noted that temperament is partly inherited, but even so, not all children will be like their parents. When the child's temperament differs dramatically from the parents', they may not abuse or neglect the child, but the parents may not know how to relate or bond with the child (Chess & Thomas, 1996; Graybar &

Boutilier, 2002). A shy and retiring boy may retreat from taking risks; his parents may force him into anxiety-provoking social situations, where he may get rejected by peers, increasing his trepidation about venturing into such situations again. His parents may then get angry at him for being afraid. In contrast, parents who understand their son's temperament might gently encourage him to take social risks in a gradual way, so that he might come to see that the feared humiliation or rejection doesn't materialize. Thus, two shy boys, growing up with different types of parenting, can readily develop different views of themselves and the world (Pretzer & Beck, 2005). And some of the resulting beliefs and attitudes may contribute to the child's developing a personality disorder.

Treating Personality Disorders: General Issues

Rachel Reiland wanted to kill herself. She called a church-sponsored hotline, and the hotline counselor convinced her not to be alone and to talk to her pastor. If she didn't show up at the pastor's by a certain time, the counselor said that he'd call an ambulance to get her. She arranged for a babysitter to watch the kids. Her pastor persuaded her to go with him to the emergency room, where she was seen by mental health clinicians and began treatment.

People with Axis I disorders often say that their problems "happened" to them—the problems are overlaid on their "usual" self. They want the problems to get better so that they can go back to being that usual self, and thus they seek treatment. In contrast, people with personality disorders don't see the problem as overlaid on their usual self; by its very nature, a personality disorder is integral to the way a person functions in the world. And so people with these disorders are less likely to seek treatment unless they also have an Axis I disorder (in which case, they typically seek help for the Axis I disorder; however, people with both a personality disorder and an Axis I disorder generally respond less well to treatments that target the Axis I disorder; Piper & Joyce, 2001).

Addressing and reducing the symptoms of a personality disorder can be challenging because patients' entrenched maladaptive beliefs and behaviors can lead them to be less motivated during treatment and less likely to collaborate with the therapist. Treatment that targets personality disorders generally lasts longer than does treatment for Axis I disorders. Unfortunately, there is little research on treatment for most personality disorders. The next section summarizes what is known about treating personality disorders in general; later in the chapter we discuss treatments for the specific personality disorders for which there are substantial research results.

Targeting Neurological Factors in Personality Disorders

Treatments for personality disorders that target neurological factors include antipsychotics, antidepressants, mood stabilizers, or other medications. Generally, however, such medications are only effective for comorbid Axis I symptoms and not very helpful for symptoms of personality disorders *per se* (Paris, 2005; 2008). Nevertheless, some of these medications may provide temporary relief of some symptoms (Paris, 2003; Soloff, 2000).

Targeting Psychological Factors in Personality Disorders

Both cognitive-behavior therapy (CBT) and psychodynamic therapy have been used to treat personality disorders. Both therapies focus on core issues that are theorized to give rise to the disorders; they differ in terms of the specific nature of the inferred core issues. Psychodynamic therapy addresses unconscious drives and motivations, whereas CBT addresses maladaptive views of self and others and negative beliefs that give rise to the problematic feelings, thoughts, and behaviors of the personality disorder (Beck, Freeman, & Davis, 2004). In treating all personality disorders, CBT is intended to increase the patient's sense of self-efficacy and mastery and to modify the negative, unrealistic beliefs that lead to maladaptive behaviors.

In addition, because people with personality disorders may not be motivated to address the problems associated with the disorder, treatment may employ motivational enhancement strategies to help patients identify goals and become willing to work with the therapist. In general, guidelines for treating personality disorders should be comprehensive, consistent, and flexible enough to address the myriad types of problems that these disorders create for the person and for others (Critchfield & Benjamin, 2006; Livesley, 2007).

Treatment that targets psychological factors has been studied in depth only for borderline personality disorder; we examine such treatment in the section discussing that personality disorder.

Targeting Social Factors in Personality Disorders

Guidelines for treating personality disorders also stress the importance of the relationship between therapist and patient, who must collaborate on the goals and methods of therapy (Critchfield & Benjamin, 2006). In fact, the relationship between patient and therapist may often become a focus of treatment as the patient's typical style of interacting with others plays out in the therapy relationship. This relationship often provides an opportunity for the patient to become aware of his or her interaction style and to develop new ways to interact with others (Beck, Freeman, & Davis, 2004).

Family education, family therapy, or couples therapy can provide a forum for family members to learn about the patient's personality disorder and to receive practical advice about how to help the patient—for example, how to respond when the patient gets agitated or upset. Family therapy can provide support for families as they strive to change their responses to the patient's behavior, thereby changing the reinforcement contingencies (Ruiz-Sancho, Smith, & Gunderson, 2001). For instance, if family members are trying to respond differently to a patient's overly dramatic and emotional requests for money ("I just have to buy that dress, or I won't be able to go out in public"), family therapy can help them use more effective and less punitive ways of communicating and learn to set limits (for instance, not give more money to the patient).

In addition, interpersonal or group therapy can highlight and address the maladaptive ways in which patients relate to others. Therapy groups also provide a forum for patients to try out new ways of interacting (Piper & Ogrodniczuk, 2005). For example, if a man thinks and acts as if he is better than others, the comments and responses of other group members can help him understand how his haughty and condescending way of interacting creates problems for him.

Key Concepts and Facts About Diagnosing Personality Disorders

- A personality disorder is characterized by maladaptive personality traits that begin by young adulthood and continue through adulthood; these traits are relatively inflexible, are expressed across a wide range of situations, and lead to distress or impaired functioning. A personality disorder affects three areas of functioning: affect, behavior (including social behavior), and cognition.
- The diagnostic criteria for personality disorders were based on the assumptions that maladaptive personality traits begin in childhood and are stable throughout life. These assumptions led to the disorders' being placed on a separate axis (Axis II) of DSM-IV-TR. Subsequent research indicates that some Axis I disorders begin in childhood and that symptoms of personality disorders may improve over time.
- Personality disorders may be assessed through diagnostic interviews, personality inventories, or questionnaires. The clinician may make the diagnosis based on the pattern of the patient's behavior and, given the preponderance of interpersonal problems that arise with personality disorders, may also rely on supplemental reports from family or friends.

- In DSM-IV-TR, personality disorders are grouped into three clusters: Cluster A, characterized by odd or eccentric behaviors related to features of schizophrenia; Cluster B, characterized by dramatic and erratic behaviors and problems with emotional regulation; and Cluster C, characterized by anxious or fearful behaviors.
- The category of personality disorders in DSM-IV-TR has been criticized on numerous grounds: The disorders are categorical and not continuous; the clusters are based on common superficialities not necessarily supported by research; the criteria for the disorders within a cluster overlap substantially; some of the disorders are not distinguished sufficiently from Axis I disorders; the criteria for specific disorders aren't supported by research; and the disorders and the criteria do not correspond to the types of personality problems observed by mental health clinicians, as is evident in the high prevalence of personality disorder not otherwise specified.
- The neuropsychosocial approach explains how personality disorders develop by highlighting the interactions among three sorts of factors:
 - Neurological factors involve the effects of genes on temperament.
 - Psychological factors include temperament, operant conditioning, and dysfunctional beliefs.
 - Social factors include insecure attachment that can result from childhood abuse or neglect.
- Treatments for personality disorders include medications for comorbid symptoms, CBT or psychodynamic therapy, and family education and therapy, as well as couples, interpersonal, and group therapy.

Making a Diagnosis

- Reread Case 13.1 about Sarah, and determine whether or not her symptoms meet the general diagnostic criteria for a personality disorder, as noted in Table 13.1. Specifically, list which criteria apply and which do not. If you would like more information to determine whether she had a personality disorder, what information—specifically—would you want, and in what ways would the information influence your decision?

Odd/Eccentric Personality Disorders

Cluster A personality disorders involve odd or eccentric behaviors and ways of thinking. Patients who have a Cluster A personality disorder are likely to develop an Axis I disorder that involves psychosis, such as schizophrenia or delusional disorder (Oldham et al., 1995; see Chapter 12). The three personality disorders in this cluster—paranoid, schizoid, and schizotypal personality disorders—are considered to be on the less severe end of the spectrum of schizophrenia-related disorders. We'll examine each of the three Cluster A personality disorders in turn and then consider what is known about the factors that give rise to them and about how to treat them. Rachel Reiland did not exhibit symptoms characteristic of this group of personality disorders, and so we will not discuss her again until we discuss Cluster B personality disorders.

Paranoid Personality Disorder

The essential feature of **paranoid personality disorder** is persistent and pervasive mistrust and suspiciousness, accompanied by a bias to interpret other people's motives as hostile (see Table 13.4, Criterion A). Someone with this personality disorder may distrust co-workers and family members, and even (falsely) believe that his or her partner is having an affair, despite the partner's denials. The patient's accusations create a difficult situation for the partner who is not having an affair but can't "prove" it to the patient's satisfaction.

Paranoid personality disorder

A personality disorder characterized by persistent and pervasive mistrust and suspiciousness, accompanied by a bias to interpret other people's motives as hostile.

Table 13.4 ▶ DSM-IV-TR Diagnostic Criteria for Paranoid Personality Disorder

- A.** A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- (1) suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
 - (2) is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
 - (3) is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
 - (4) reads hidden demeaning or threatening meanings into benign remarks or events
 - (5) persistently bears grudges (i.e., is unforgiving of insults, injuries, or slights)
 - (6) perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack
 - (7) has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner
- B.** Does not occur exclusively during the course of schizophrenia [Chapter 12], a mood disorder with psychotic features [Chapter 6], or another psychotic disorder [Chapter 12] and is not due to the direct physiological effects of a general medical condition.

People with paranoid personality disorder are better able to evaluate whether their suspicions are based on reality than are people with paranoid schizophrenia. Moreover, the sources of their perceived threats are not likely to be strangers or bizarre types of signals (such as radio waves), as is the case with paranoid schizophrenia, but rather known individuals (Skodol, 2005). If the symptoms arise while a person is using substances or during a psychotic episode of schizophrenia or a mood disorder, then paranoid personality disorder is not diagnosed. As you'll see in Case 13.2, about Ms. X., it may not be immediately apparent from a patient's report what is "true" and what is a paranoid belief.

CASE 13.2 ► FROM THE OUTSIDE: Paranoid Personality Disorder

The Case of Ms. X. by Daphne C. Brazile, MD

Ms. X. is a middle-aged African-American woman who has lived in the area all of her life. She began seeking treatment . . . after her family members had noted that, to them, she was acting strangely. Ms. X. stated that she believed that her family members were out to make her crazy and convince her neighbors of the same. She stated the reason for this was because she was the "darkest one" in her family. Ms. X. was a fair-skinned black woman. She was born to a dark-skinned black mother and a white father. She was the darkest sibling of her family. Because of this, she felt that her family had treated her and her mother unjustly. She stated that as a child, she was instructed to look after her lighter-skinned older sisters, whom the family held in high regard. She stated that she did not complete high school because she had to care for her older sister's children. She described that she would be instructed to "cook and clean" for them, as though she were their slave, and be available to them whenever they needed her. . . . Because of this, [she claimed] she was not able to have a social life. After Ms. X. married, she continued to receive the same treatment from her sisters. She stated that her children were treated unfairly, because of their darker skin as well. . . . As she got older, Ms. X. stated that her sisters, who were part of the elite society, would "embarrass" her while around their socialite friends. She believed this to be due to her darker skin color. She stated that her sisters convinced her neighbors that she was a "bad" person, and because of this, her neighbors would do "evil" things to spite her.

Ms. X. met with her sisters to discuss this issue. When confronted, the sisters denied that they were treating her negatively. They acknowledged that their skin was fairer than hers but denied that they were treating her in such a way. They believed that their sister was "delusional." Ms. X. refused to believe her sisters, and when confronted with the idea that her family was not in any way harming her, she would shift the conversation to another topic.

(Paniagua, 2001, pp. 135–136)

People with paranoid personality disorder distrust others and tend to interpret other people's remarks or behaviors as having malevolent intent. They are likely to maintain these interpretations despite evidence to the contrary.

As was the case with Ms. X.'s refusal to believe her sisters, people with paranoid personality disorder cannot readily be persuaded that their paranoid beliefs do not reflect reality, although they can recognize that there are multiple ways to interpret other people's reactions and behaviors. Although less obvious in the case of Ms. X., other common characteristics of people with this personality disorder include a strong desire to be self-sufficient and in control, which stems from a distrust of others, and a tendency to be critical of others and blame them for problems that arise. People with this disorder may also be unable to accept criticism *from* others. In response to stress, they may become briefly psychotic, with their paranoid beliefs reaching delusional proportions.

In addition, people with paranoid personality disorder tend to be difficult to get along with because their suspiciousness frequently leads them to be secretive or "cold," argumentative, or complaining or to bear a grudge. These behaviors often elicit hostility or anger in others, which then confirms the individual's suspicious beliefs. Table 13.5 provides additional information about paranoid personality disorder.

Table 13.5 ▶ Paranoid Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Between 0.5% and 4.5% of the general population is estimated to have paranoid personality disorder (American Psychiatric Association, 2000; Grant, Hasin, et al., 2004). Among patients receiving treatment in outpatient mental health clinics, prevalence estimates are higher (2–10%), and among hospitalized patients, prevalence estimates are in the range of 10–30%.
Comorbidity
<ul style="list-style-type: none"> People with paranoid personality disorder may also have another Axis II personality disorder, usually another Cluster A (odd/eccentric) personality disorder (schizoid or schizotypal) or narcissistic, avoidant, or borderline personality disorder.
Onset
<ul style="list-style-type: none"> Symptoms can first appear in childhood or adolescence, when the individual appears hypersensitive, has difficulties with peers, and has odd thoughts or fantasies or uses language unconventionally.
Course
<ul style="list-style-type: none"> The symptoms of paranoid personality disorder are relatively stable over time (Seivewright, Tyrer, & Johnson, 2002).
Gender Differences
<ul style="list-style-type: none"> Based on surveys in the general population, there is no clear gender difference in the prevalence of paranoid personality disorder. However, among people with this disorder, men are more likely than women to come to the attention to mental health professionals (Morey, Alexander, & Boggs, 2005).
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

Part of the challenge for clinicians is that the symptoms of paranoid personality disorder may not always imply that a person has the disorder. When the suspicious beliefs of someone with paranoid personality disorder center on racial or ethnic conflicts, as they did for Ms. X., it may be difficult for a clinician to determine the extent to which such beliefs may reflect the actual state of affairs or, alternatively, are pervasive misperceptions and misinterpretations (Paniagua, 2001). Similarly, the clinician must try to understand how an individual's life events might give rise to beliefs and behaviors that, in error, could be considered paranoid. For example, an immigrant who experienced harassment might exhibit appropriately guarded behavior patterns in unfamiliar circumstances, such as not speaking much or responding to others with minimal bodily or facial expressions of emotion; such behaviors may in turn inadvertently elicit negative emotions and behaviors from others who don't understand the person's cultural context.

To summarize, paranoid personality disorder involves a chronic pattern of suspiciousness and mistrust that often creates interpersonal problems because of the guarded ways in which the patient interacts with others.

Schizoid Personality Disorder

Schizoid personality disorder is characterized by a restricted range of emotions in social interactions and few—if any—close relationships (American Psychiatric Association). Table 13.6 lists the DSM-IV-TR diagnostic criteria. People with schizoid personality disorder often lack social skills and may not pick up on or understand the normal social cues required for smooth social interactions—for instance, they may return someone's smile with a stare. Such difficulties with social cues can lead to problems in jobs that require interacting with others.

In addition, people with schizoid personality disorder may react passively to adverse events: They may seem to lack initiative and drift through life. People with

Schizoid personality disorder

A personality disorder characterized by a restricted range of emotions in social interactions and few—if any—close relationships.

Table 13.6 ▶ DSM-IV-TR Diagnostic Criteria for Schizoid Personality Disorder

A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

- (1) neither desires nor enjoys close relationships, including being part of a family
- (2) almost always chooses solitary activities
- (3) has little, if any, interest in having sexual experiences with another person
- (4) takes pleasure in few, if any, activities
- (5) lacks close friends or confidants other than first-degree relatives
- (6) appears indifferent to the praise or criticism of others
- (7) shows emotional coldness, detachment, or flattened affectivity

B. Does not occur exclusively during the course of schizophrenia [Chapter 12], a mood disorder with psychotic features [Chapter 6], another psychotic disorder [Chapter 12], or a pervasive developmental disorder [Chapter 14] and is not due to the direct physiological effects of a general medical condition.

this disorder appear to be emotionless and often don't express anger, even when provoked. And in fact, they often report that they rarely experience strong emotions such as joy and anger (Livesley, 2001). In contrast to those with paranoid personality disorder, people with schizoid personality disorder generally aren't suspicious and are indifferent to other people (Skodol, 2005).

Not surprisingly, patients with this personality disorder function best when isolated from others, which is true for the woman in Case 13.3; in fact, people with this personality disorder generally don't marry or express a desire for sexual intimacy. In response to stress, they may have a very brief psychotic episode (from minutes to hours). Table 13.7 presents some additional facts about schizoid personality disorder.

CASE 13.3 ▶ FROM THE OUTSIDE: Schizoid Personality Disorder

A 33-year-old woman with three children became a cause of concern to social services because of her limited caring abilities. Investigations led to two of her children being taken into [foster] care and, after a further period of 2 years, her third child was also taken away. At this time she was referred to psychiatric services because she was felt to be isolated from society and had such poor social function. It proved very difficult to engage her as she would go to great length to avoid contact and it was uncertain to what extent she required compulsory treatment. Eventually, she was admitted under a compulsory order after threatening a community worker. . . . After discharge from [the] hospital she was transferred to supportive housing but resented the frequent monitoring of her progress, which she perceived as intrusion and tried to avoid contact. . . . She also developed a marked tremor on antipsychotic drugs and these were steadily withdrawn and stopped altogether after 1 year and she remained completely free of psychotic symptoms. However, the improvement revealed marked schizoid personality features and she found it difficult to adjust to interacting with others in her [community residence] and tried wherever possible to avoid them. . . . She functioned better with no contact and so a transfer was agreed to a supported [apartment] where she would be left undisturbed apart from one visit each week from a support worker and a full review every 6 months. After 2 years she remains well on no treatment and is very happy with her life, which despite little interaction with other people now includes regular contact with her family.

(Tyrer, 2002, p. 470)

Table 13.7 ▶ Schizoid Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Approximately 3% of the general population is estimated to have schizoid personality disorder (Grant, Hasin, et al., 2004).
Comorbidity
<ul style="list-style-type: none"> A common comorbid Axis I disorder is major depressive disorder. Common comorbid Axis II disorders are the other Cluster A (odd/eccentric) personality disorders (paranoid and schizotypal personality disorders) and avoidant personality disorder. Half of the people diagnosed with schizoid personality disorder will also be diagnosed with schizotypal personality disorder (McGlashan et al., 2000).
Onset
<ul style="list-style-type: none"> Those who develop schizoid personality disorder were often socially isolated underachievers who were teased by their classmates as children and adolescents.
Course
<ul style="list-style-type: none"> Schizoid personality disorder is relatively stable over time (Seivewright, Tyrer, & Johnson, 2002).
Gender Differences
<ul style="list-style-type: none"> This personality disorder is diagnosed more often in men than in women. Women with this personality disorder are often more impaired than their male counterparts.
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

As with paranoid personality disorder, mental health clinicians need to make sure that the diagnosis of schizoid personality disorder isn't applied to people from different cultural backgrounds because of behaviors that are appropriate in their culture of origin. For instance, among the Hindu of India, it is considered saintly to be detached from and unmoved by events, and such traits would thus not be considered symptoms of a personality disorder in that culture (Castillo, 1997). Similarly, symptoms of schizoid personality disorder must be distinguished from superficially similar behaviors exhibited by immigrants or people who move from rural to urban environments and find the experience so overstimulating that they "shut down" emotionally for the first few months: Such individuals may engage in solitary activities and appear emotionally flat as they attempt to cope with the novel and demanding environment (American Psychiatric Association, 2000).

In sum, schizoid personality disorder involves a chronic pattern of limited emotional expression and diminished social understanding, few relationships, and little desire for relationships.

Schizotypal Personality Disorder

People with **schizotypal personality disorder** have eccentric thoughts, perceptions, and behaviors, in addition to having very few close relationships, like those with schizoid personality disorder (American Psychiatric Association, 2000).

What Is Schizotypal Personality Disorder?

According to the DSM-IV-TR diagnostic criteria, schizotypal personality disorder has nine symptoms (see Table 13.8, Criterion A), which can be organized into three distinct groups (Calkins et al., 2004; Raine, 2006; Reynolds et al., 2000):

- *Cognitive-perceptual*
 - magical thinking, in which the person believes that he or she has control over external events, as occurs with superstitious beliefs
 - unusual perceptual experiences, such as sensing the presence of another person when no one is there or hearing a voice on the radio murmuring one's name

Schizotypal personality disorder

A personality disorder characterized by eccentric thoughts, perceptions, and behaviors, in addition to having very few close relationships.

- *ideas of reference*, in which the individual interprets ordinary events to have particular meaning for him or her (a milder form of delusions of reference, described in Chapter 12)
- suspiciousness or paranoid ideation, which consists of paranoid beliefs that are less entrenched than paranoid delusions
- *Interpersonal*
 - no close friends because of a preference for being alone
 - constricted affect, showing only a narrow range of emotions
 - social anxiety that arises because of a general suspiciousness about other people
 - suspiciousness or paranoid ideation about other people
- *Disorganized*
 - odd/eccentric behaviors, such as wearing mismatched or unkempt clothing, avoiding eye contact, or being unable to make conversation
 - odd speech, such as being overly vague or elaborate or using words idiosyncratically (as in “My co-worker isn’t talkable”)

IK, in Case 13.4, had symptoms that represent all three groups highlighted in Table 13.8. Additional facts about schizotypal personality disorder are listed in Table 13.9.

Table 13.8 ▶ DSM-IV-TR Diagnostic Criteria for Schizotypal Personality Disorder

A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) ideas of reference (excluding delusions of reference)
- (2) odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or “sixth sense”; in children and adolescents, bizarre fantasies or preoccupations)
- (3) unusual perceptual experiences, including bodily illusions
- (4) odd thinking and speech (e.g., vague, circumstantial, metaphorical, overly elaborate, or stereotyped)
- (5) suspiciousness or paranoid ideation
- (6) inappropriate or constricted affect
- (7) behavior or appearance that is odd, eccentric, or peculiar
- (8) lack of close friends or confidants other than first-degree relatives
- (9) excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self.

B. Does not occur exclusively during the course of schizophrenia [Chapter 12], a mood disorder with psychotic features [Chapter 6], another psychotic disorder [Chapter 12], or a pervasive developmental disorder [Chapter 14].

Note: Cognitive-perceptual symptoms are in green, interpersonal symptoms are in purple, and disorganized symptoms are in orange. Note also that Criterion A5 is considered to be both a cognitive-perceptual symptom and an interpersonal symptom.

CASE 13.4 ▶ FROM THE OUTSIDE: Schizotypal Personality Disorder

IK is a 33-year-old man who had both schizotypal personality disorder and obsessive-compulsive disorder (OCD) for at least 17 years.

His schizotypal symptoms included poor interpersonal relatedness, ideas of reference (not delusional), social anxiety, unusual perceptual experiences (such as seeing things in

the periphery, but not there when viewed directly), constricted affect, and some paranoid ideation (in particular with regard to police officers, but his father reported that this was unrealistic).

IK's social skills deficits were primarily conversation skills, inappropriate affect, poor assertion skills, and lack of eye contact with the therapist and family members. He was also prone to aggressive outbursts in the home, often breaking objects due to frustration.

(McKay & Neziroglu, 1996, pp. 190–191)

Table 13.9 ▶ Schizotypal Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none">Approximately 2–3% of the general population has schizotypal personality disorder.
Comorbidity
<ul style="list-style-type: none">Common comorbid Axis I disorders are major depressive disorder, social phobia, and panic disorder (American Psychiatric Association, 2000; Raine, 2006).Common comorbid Axis II disorders include other Cluster A (odd/eccentric) personality disorders (schizoid and paranoid; McGlashan et al., 2000), as well as borderline, avoidant, and obsessive-compulsive personality disorders (American Psychiatric Association, 2000; Raine, 2006).
Onset
<ul style="list-style-type: none">Symptoms arise by early adulthood.In childhood and adolescence, symptoms may include social isolation and social anxiety, academic underachievement, hypersensitivity, odd fantasies and thoughts, and idiosyncratic use of language.
Course
<ul style="list-style-type: none">Although schizotypal personality disorder most commonly has a stable course, symptoms may improve over time for some people (Fossati, Madeddu, & Maffei, 2003). In fact, for almost a quarter of patients, symptoms improve to the point where they no longer meet all the diagnostic criteria (Grilo et al., 2004).Among other patients with this disorder the opposite is true: A small percentage go on to develop schizophrenia or another psychotic disorder (Grilo et al., 2004).
Gender Differences
<ul style="list-style-type: none">Schizotypal personality disorder is slightly more common among men than women.
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

Distinguishing Between Schizotypal Personality Disorder and Other Disorders

Schizotypal personality disorder differs from schizoid personality disorder in that the former includes cognitive-perceptual symptoms—such as IK’s ideas of reference and seeing things with peripheral vision that could not be seen with a direct gaze—and odd behavior. Nevertheless, research suggests that these two disorders may not be distinct from each other; half of those with schizoid personality disorder are also diagnosed with schizotypal personality disorder (McGlashan et al., 2000). Some researchers propose that schizoid personality disorder may simply be a subtype of schizotypal personality disorder (Raine, 2006).

Schizotypal personality disorder is generally thought of as a milder form of schizophrenia, and some researchers propose moving this disorder to Axis I, with schizophrenia (First et al., 2002). Sometimes, it can be difficult to determine whether a person’s symptoms are severe enough to merit a diagnosis of schizophrenia. To help with diagnosis, clinicians may assess the degree to which patients are convinced of the reality of their perceptions or beliefs by probing their ability to recognize other interpretations (Skodol, 2005). When under stress, people with schizotypal personality disorder may become psychotic for minutes to hours.

The DSM-IV-TR explicitly notes that cognitive and perceptual distortions may occur as part of culturally sanctioned or religious rituals or practices, and these should be distinguished from symptoms of schizotypal personality disorder. Examples include voodoo experiences, mind reading, and receiving “the evil eye” (Campinha-Bacote, 1992; Paniagua, 2001).

Understanding Odd/Eccentric Personality Disorders

The odd or eccentric elements of Cluster A personality disorders are less intense manifestations of features of schizophrenia (Chapter 12): Paranoid personality disorder involves paranoid beliefs; schizoid personality disorder involves flat affect and a detachment from others; and schizotypal personality disorder involves cognitive alterations similar to those that arise in schizophrenia—delusions and unusual perceptions. Schizotypal personality disorder is the most thoroughly researched among the odd/eccentric personality disorders; thus, in this section we focus predominantly on the neuropsychosocial factors that give rise to this particular disorder but also include information about the other odd/eccentric personality disorders where appropriate.

Neurological Factors in Odd/Eccentric Personality Disorders

Most of the neurological factors that contribute to schizophrenia have also been found to contribute to schizotypal personality disorder: genes and prenatal environment, such as maternal illness and malnourishment, and birth complications (Raine, 2006; Torgersen et al., 2000). In both disorders, researchers have documented abnormalities in brain structure (in the frontal and temporal lobes, the thalamus, and the hippocampus) and abnormalities in neural function (activity of dopamine, serotonin, and glutamate). These abnormalities are generally not as severe in people with schizotypal personality disorder as in people with schizophrenia (Buchsbaum et al., 2002; Siever & Davis, 2004).

Genes play a role in all Cluster A personality disorders (paranoid, schizoid, and schizotypal): First-degree relatives of patients with Cluster A personality disorders are more likely to develop a schizophrenia-related disorder than are people who are not related to such patients (Chang et al., 2002; Siever & Davis, 1991). This makes sense given that schizophrenia shares some symptoms with each of the odd/eccentric personality disorders. Additional evidence that genes play a role is the fact that the rates of schizotypal personality disorder are higher among family members of people with schizophrenia than among the general population (Siever & Davis, 2004; Tienari et al., 2003).

Psychological Factors in Odd/Eccentric Personality Disorders

Like people with schizophrenia, those with schizotypal personality disorder tend to have specific cognitive deficits. These include problems with attention (distinguishing relevant from irrelevant stimuli), memory, and executive function (used in problem solving, planning, and judgment) (Voglmaier et al., 2000). According to Beck and colleagues (2004), schizotypal personality disorder is unusual among the personality disorders in that the primary distortions are in mental processes (e.g., perceptions) rather than in mental contents. However, problems with social interactions can arise from the cognitive deficits: People with this personality disorder tend to have an impaired *theory of mind*—as reflected by difficulty recognizing emotions in others (Waldeck & Miller, 2000) and taking another’s point of view or recognizing another’s mental state (Langdon & Coltheart, 2001). Although people with schizotypal personality disorder have cognitive deficits, they generally have better cognitive skills than do people with schizophrenia (Trestman et al., 1995).

In addition, core maladaptive beliefs and strategies of people with each of the odd/eccentric personality disorders may differ (see Table 13.10), but all these patients

Table 13.10 ▶ Maladaptive Views, Beliefs, and Strategies of Individuals with Odd/Eccentric Personality Disorders

Personality Disorder	View of Self	View of Others	Main (Negative) Beliefs	Main Strategies (Overt Behavior)
Paranoid	Righteous, innocent, vulnerable	Interfering, malicious, discriminatory, malevolent	"People are dangerous." "Others' motives are suspect." "I must always be on guard." "I cannot trust people."	Remain wary. Look for hidden motives, accuse, counterattack.
Schizoid	Self-sufficient, loner	Intrusive	"I need plenty of space." "Others are unrewarding." "Relationships are messy and undesirable."	Maintain isolation.
Schizotypal	Unreal, detached, loner; vulnerable, socially conspicuous; supernaturally sensitive and gifted	Untrustworthy, malevolent	The patient holds odd or superstitious beliefs such as a belief in telepathy or "sixth sense." "It's better to be isolated from others."	Watch for and neutralize malevolent attention from others. Keep to oneself. Be vigilant for supernatural forces or events.

Source: Beck, Freeman, & Davis, 2004, pp. 21, 36, 48–49. Copyright 2004 by Guilford Publications, Inc. For more information see the Permissions section.

tend to avoid others and isolate themselves (Beck, Freeman, & Davis, 2004; Farmer & Nelson-Gray, 2005). People with any of these three disorders also often behave in unusual ways (hence the label "odd/eccentric"), and these behaviors then make them noticeable to others. And their obvious unusual behavior can make other people more likely to mistreat them (intentionally or not), confirming their beliefs about themselves and other people. People with these disorders also pay attention to, remember, and interpret stimuli in ways that are consistent with their beliefs and that thus reinforce their isolation and avoidance of other people.

Social Factors in Odd/Eccentric Personality Disorders

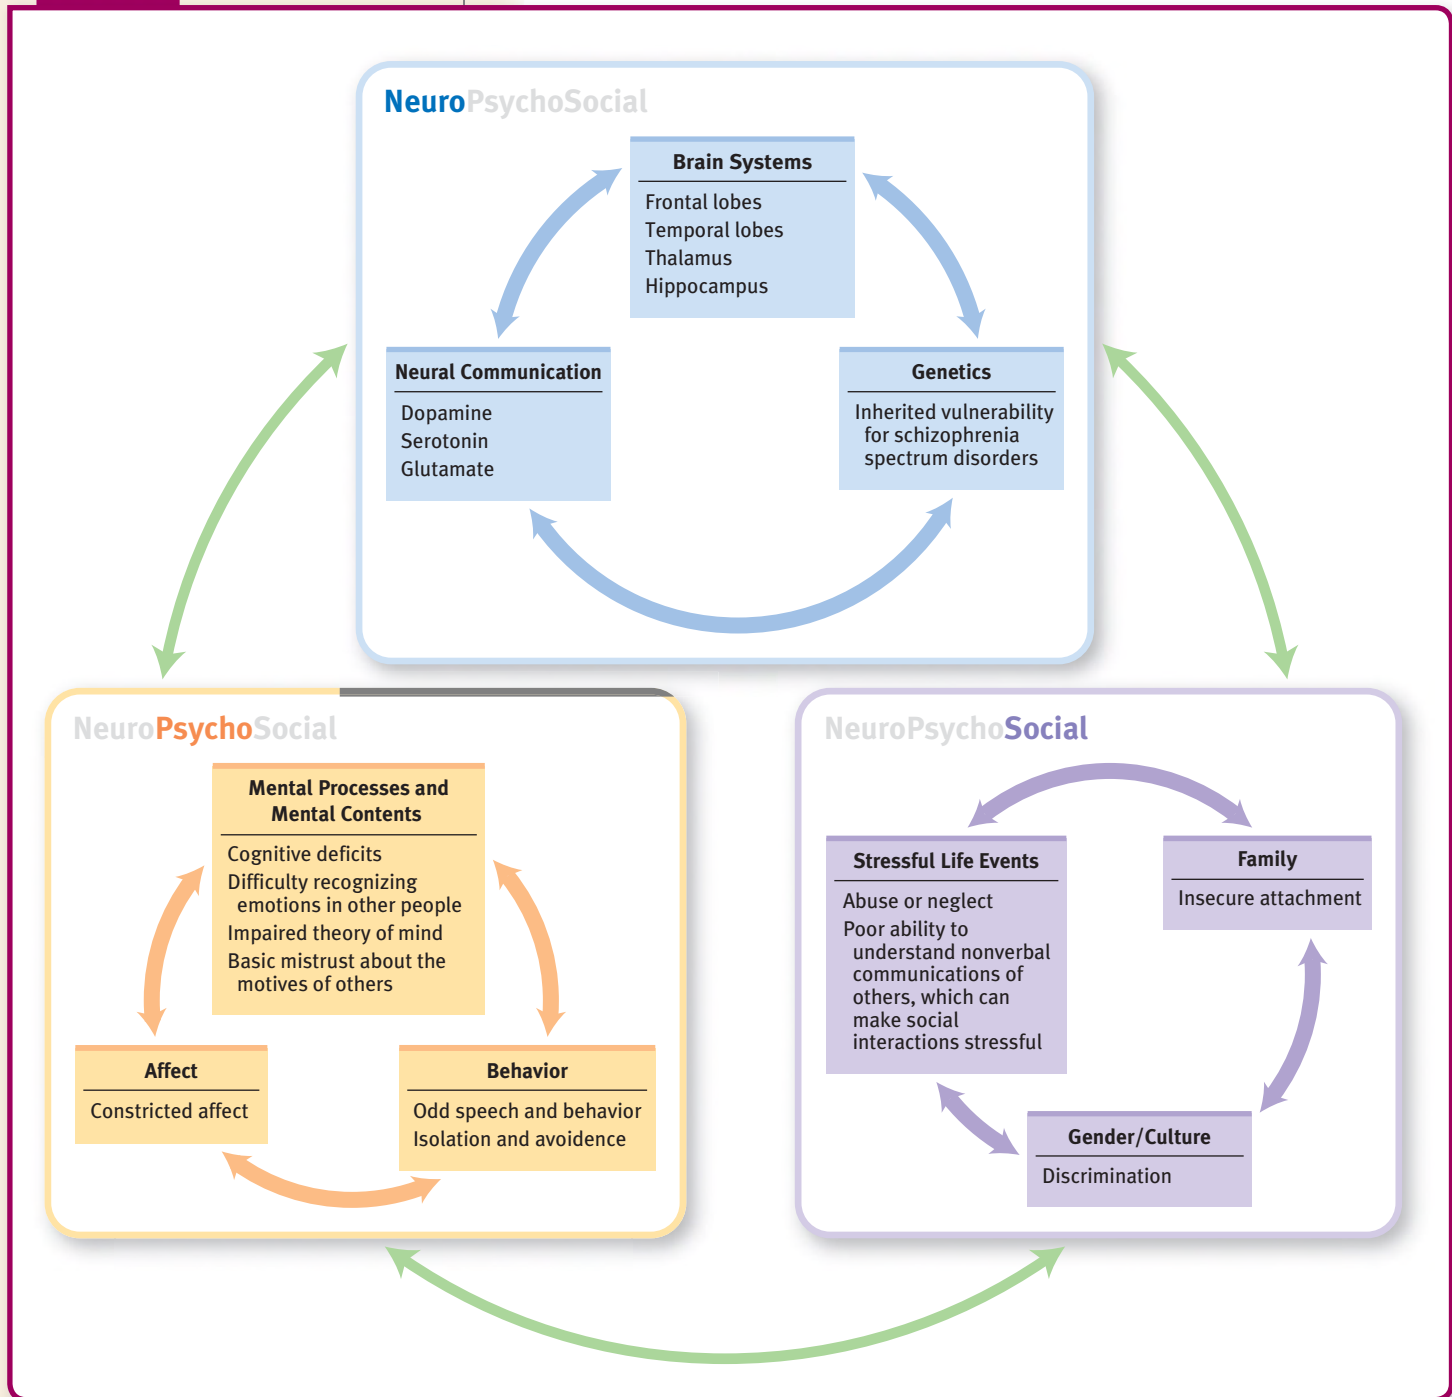

In contrast to their lesser role in schizophrenia, certain social factors appear to play a relatively large role in the onset of schizotypal personality disorder. These social factors include physical abuse or neglect, insecure attachment to parents, and discrimination (Berenbaum et al., 2008; Raine, 2006; Wilson & Constanzo, 1996)—all stressful events. In fact, some of these social factors may be related to each other: Insecure attachment may, at least in part, arise from abuse or neglect. Children who develop schizotypal personality disorder are more likely to have experienced trauma, abuse, and neglect than are those who went on to develop most other personality disorders (Yen et al., 2002). These negative childhood experiences influence patients' views of other people as untrustworthy and having malevolent motives.

FEEDBACK LOOPS IN ACTION: Understanding Schizotypal Personality Disorder

With schizotypal personality disorder, as with schizophrenia (Chapter 12), neuropsychosocial factors create feedback loops (see Figure 13.4). For instance, early social stressors such as neglect and trauma can contribute to brain abnormalities, particularly if a genetic or other neurological vulnerability exists before birth. The neurological changes, in turn, contribute to disturbances in cognitive and emotional functioning (Raine, 2006). These cognitive and emotional disturbances then can lead to problems in social interactions and increased stress (Skodol, Gunderson et al., 2002), which then affect neurological functioning. Moreover, trauma, neglect, and insecure attachment may give rise to a paranoid attributional style and a discomfort with others (Raine, 2006).

Figure 13.4

13.4 ► Feedback Loops in Action: Schizotypal Personality Disorder

Treating Odd/Eccentric Personality Disorders

Unfortunately, very little research has been conducted to evaluate treatments for these personality disorders. People with an odd/eccentric personality disorder tend not to be interested in treatment and, if urged or coerced into it, are often reluctant participants at best. Treatment may create significant anxiety for the patient. Thus, the particular challenge of treating people with odd/eccentric personality disorders

is their tendency not to collaborate with the therapist to develop goals for treatment (Beck, Freeman, & Davis, 2004; Farmer & Nelson-Gray, 2005).

Nevertheless, when such patients do participate in CBT, they can develop more adaptive strategies, such as improved social skills (which makes them less likely to be conspicuous, and in turn leads them to feel safer when with others). CBT may also employ relaxation techniques, exposure to avoided social situations, and cognitive restructuring of distorted views of self and others and of dysfunctional beliefs (Beck, Freeman, & Davis, 2004; Farmer & Nelson-Gray, 2005).

Most of the medications that effectively treat symptoms of schizophrenia can also treat symptoms of schizotypal personality disorder, although the medications are often taken at a lower doses (Koenigsberg et al., 2003; Raine, 2006; see Chapter 12). The psychosocial treatments employed with people who have schizophrenia—CBT, social skills training, and family therapy—may be employed with people who have schizotypal personality disorder, but very few studies have evaluated the use of such treatments for people diagnosed with schizotypal personality disorder. One preliminary study investigated such treatments for people who had some symptoms of schizotypal personality—but not enough symptoms to receive the diagnosis of the personality disorder; the results suggest that social skills training can be effective (Liberman & Robertson, 2005).

Key Concepts and Facts About Odd/Eccentric Personality Disorders

- The essential feature of paranoid personality disorder is a persistent and pervasive mistrust and suspiciousness, which is accompanied by a bias to interpret other people's motives as hostile. Although paranoid personality disorder and paranoid schizophrenia both involve suspicious beliefs, people with the personality disorder have some capacity to evaluate whether their suspicions are based on reality; they also tend to be suspicious about people they know. In contrast, the beliefs of people with paranoid schizophrenia are delusional, and they perceive threats as coming from strangers or objects.
- Schizoid personality disorder is characterized by a restricted range of emotions in social interactions and few—if any—close relationships; people with this disorder have poor social skills. They report rarely experiencing strong emotions, and they prefer to be—and function best when—isolated from others.
- Schizotypal personality disorder is marked by eccentric thoughts, perceptions, and behaviors, as well as by having very few close relationships. This personality disorder is characterized by three groups of symptoms: cognitive-perceptual, interpersonal, and disorganized.
- Schizotypal personality disorder is viewed as a milder form of schizophrenia. Many of the factors that give rise to schizophrenia also appear to give rise to schizotypal personality disorder: genes and the prenatal environment; problems with attention, memory, and executive function as well as an impaired theory of mind; and physical abuse or neglect in childhood, insecure attachment, and discrimination.
- Paranoid, schizoid, and schizotypal personality disorders are on the spectrum of schizophrenia-related disorders, and close relatives of people with any of these odd/eccentric personal-

ity disorders are more likely to have schizophrenia. Schizotypal personality disorder involves neurological abnormalities that are less severe than those associated with schizophrenia.

- People with odd/eccentric personality disorders are reluctant participants in treatment. Treatment may address fundamental issues, such as isolation and suspiciousness. Treatment for schizotypal personality disorder may include antipsychotic medication (although at lower doses than used for psychotic disorders), CBT, social skills training, and family therapy.

Making a Diagnosis

- Reread Case 13.2 about Ms. X., and determine whether or not her symptoms meet the criteria for paranoid personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 13.3 about the 33-year-old woman, and determine whether or not her symptoms meet the criteria for schizoid personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 13.4 about IK, and determine whether or not his symptoms meet the criteria for schizotypal personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Dramatic/Erratic Personality Disorders

In her memoir, Rachel Reiland recalls an occasion when a minor matter set off an escalating fight between her and her husband. She raged at him until she realized that she might drive him away. Then, she decided to leave him before he had a chance to leave her. She ran out of the house barefoot, then ran for miles through the city on glass-strewn sidewalks. After several hours, her husband and children—who had been searching for her—pulled up their car beside her and brought her home (Reiland, 2004).

Reiland's response to this fight with her husband exemplifies the typical reactions of people with Cluster B personality disorders—impulsive, dramatic, and erratic behaviors, which arise because of difficulty regulating their emotions. In fact, emotional dysregulation and impulsive and dramatic behaviors are common to all Cluster B (dramatic/erratic) personality disorders. This commonality can sometimes make it difficult to determine which specific Cluster B personality disorder a given patient has; many of the symptoms specified in the diagnostic criteria are not unique to a single personality disorder in the cluster (Blais, Hilsenroth, & Fowler, 1999; Fosatti, Madeddu, & Maffei, 1999; Zanarini & Gunderson, 1997; Zittell & Westen, 1998). People with a dramatic/erratic personality disorder also tend to have certain types of Axis I disorders, namely substance-related disorders, mood disorders, anxiety disorders, or eating disorders (Dolan-Sewell, Krueger, & Shea, 2001; McGlashan et al., 2000; Oldham et al., 1995; Skodol, Oldham, & Gallaher, 1999; Skodol et al., 1993; Tyrer et al., 1997; Zanarini, Gunderson, & Frankenburg, 1989; Zanarini et al., 1998).

Let's examine the four Cluster B (dramatic/erratic) personality disorders: antisocial, borderline, histrionic, and narcissistic.

Antisocial Personality Disorder

One day, Reiland was in a particularly angry mood and she put the following note on the front door: *"You need to pick up the kids. I'm upstairs in the attic. Don't even think of going up there if you know what's good for you!"* At the bottom of the stairs to the attic, she taped another note: *"Stay away! Don't mess with me! You don't know what I might have up here!"* The last note was on the attic door, which was locked: *"I might die anyway, but if you dare come in here, you might all be dead! You don't know what I have up here!"* (Reiland, 2004, p. 148).

Some might say that Reiland's behavior—and her apparent lack of concern for how her husband and children might respond to the notes—had elements of **antisocial personality disorder**, which involves a persistent disregard for the rights of others. As noted in Criterion A in Table 13.11, people with antisocial personality disorder may violate rules or laws (for example, by stealing) and may lie or act aggressively, hurting others (American Psychiatric Association, 2000). They may also act impulsively, putting themselves or others at risk of harm. In addition to these behaviors, people with antisocial personality disorder shirk their responsibilities—they don't pay their bills or show up for work on time, for instance. They may also exhibit a fundamental lack of regret for or guilt about their antisocial behaviors, seeming to lack a conscience, a moral sense, or a sense of empathy. In Reiland's case, holing up

Table 13.11 ▶ DSM-IV-TR Diagnostic Criteria for Antisocial Personality Disorder

- A.** There is a pervasive pattern of disregard for and violation of the rights of others occurring since age 15 years, as indicated by three (or more) of the following:
- (1) failure to conform to social norms with respect to lawful behaviors as indicated by repeatedly performing acts that are grounds for arrest
 - (2) deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
 - (3) impulsivity or failure to plan ahead
 - (4) irritability and aggressiveness, as indicated by repeated physical fights or assaults
 - (5) reckless disregard for safety of self or others
 - (6) consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
 - (7) lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another
- B.** The individual is at least age 18 years
- C.** There is evidence of conduct disorder [Chapter 14] with onset before age 15 years
- D.** The occurrence of antisocial behavior is not exclusively during the course of schizophrenia [Chapter 12] or a manic episode [Chapter 6].

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

in the attic and writing the threatening notes probably resulted from uncontrollable emotions that ended up hurting other people (and Reiland) rather than from a disregard for others.

The diagnostic criteria for antisocial personality disorder are the most behaviorally specific of the criteria for personality disorders and even include overt criminal behaviors (Skodol, 2005). Because of this specificity, antisocial personality disorder is the most reliably diagnosed personality disorder (Skodol, 2005). Clinicians may, however, be biased in how they diagnosis this disorder: One study found that clinicians in the United Kingdom were more likely to rate a man described in a case report as having antisocial personality disorder when the man was identified as White than when he was identified as Black (Mikton & Grounds, 2007). And although the criteria are behaviorally specific, it is not clear whether people with this personality disorder who perpetrate a criminal act have a unique constellation of personality traits not shared by people with this disorder who do not perpetrate a criminal act (Silverstein, 2007).

Like other personality disorders, antisocial personality disorder manifests itself in childhood or adolescence, but DSM-IV-TR is again very specific about antisocial personality disorder: The symptoms must have arisen by age 15 (although the diagnosis cannot be made until the individual is at least 18 years old). The diagnosis for people who exhibit a similar pattern of symptoms but are younger than 18 is **conduct disorder**, which is characterized by consistently violating the rights of others (through lying, threatening, destructive and aggressive behaviors) or violating societal norms. (In Chapter 14 we discuss conduct disorder in detail.) Table 13.12 provides additional facts about antisocial personality disorder.

Table 13.12 ▶ Antisocial Personality Disorder
Facts at a Glance

Prevalence
<ul style="list-style-type: none">Between 1% and 4% of Americans are diagnosed with antisocial disorder (American Psychiatric Association, 2000; Grant, Hasin, et al., 2004).Around 60% of male prisoners in a number of countries have antisocial personality disorder (Moran, 1999).
Comorbidity
<ul style="list-style-type: none">The most common comorbid Axis I disorders are anxiety disorders, mood disorders, substance-related disorders, and somatization disorders (American Psychiatric Association, 2000; Compton et al., 2005; Sareen et al., 2004).In a clinical setting, most patients who meet the criteria for antisocial personality disorder also are diagnosed with at least one other personality disorder, typically another dramatic/erratic personality disorder (Widiger & Corbitt, 1997).
Onset
<ul style="list-style-type: none">As required by the DSM-IV-TR criteria, symptoms of conduct disorder emerge before age 15, and specific symptoms of antisocial behavior occur since age 15. The specific antisocial behaviors then continue into adulthood.
Course
<ul style="list-style-type: none">Antisocial personality disorder has a chronic course, but symptoms may improve as patients age, particularly in their 40s (Seivewright, Tyrer, & Johnson, 2002)
Gender Differences
<ul style="list-style-type: none">Antisocial personality disorder is diagnosed three times more often in men than in women.

CASE 13.5 ▶ FROM THE OUTSIDE: Antisocial Personality Disorder

John and his sister were adopted by the same family when they were respectively 1.5 and 3 years of age. From the very beginning, John was severely physically abused by his adoptive father as a result of just minor misbehaviors. Furthermore, John felt that he and his sister were neglected (lack of warmth and attention) by his adoptive parents and that he and his sister were thought of much less highly by them than their only biological son. From age 10 John and his sister were sexually abused on a regular basis by his adoptive father, and John was forced to watch when his father raped his sister. He demonstrated more and more oppositional and angry behavior, and he became a notorious thief. John left junior secondary technical school prematurely and had many short-term jobs, but he was dismissed every time because of lack of motivation, disobedience, and/or theft. As a consequence of his deviant behavior, John was placed in a juvenile correctional and observation institute when he was 16 years of age. A psychiatric report from this episode described him as a socially, emotionally, morally, and sexually underdeveloped person who was very suspicious and angry. He projected his discomfort on the outside world. After his release from the juvenile correctional institute (when he was 18 years of age), John was arrested because of violent pedophilic rape, theft, and fraud. John was sentenced to forensic psychiatric treatment. But soon after his release, when he was 24, John was sentenced to life imprisonment because he committed an excessively violent sexual homicide on a 9-year-old boy.

(Martens, 2005, pp. 117–118)

Antisocial personality disorder
A personality disorder characterized by a persistent disregard for the rights of others.

Conduct disorder
A psychological disorder that typically arises in childhood and is characterized by the violation of the basic rights of others or of societal norms that are appropriate to the individual's age.

The Role of Conduct Disorder

One of the diagnostic criteria for antisocial personality disorder is evidence of conduct disorder in childhood. Although a person need not have been *diagnosed* with that disorder during childhood, the person should have exhibited symptoms of it, as John in Case 13.5 did. Given this diagnostic requirement, it is not surprising that having conduct disorder in childhood is strongly associated with antisocial personality disorder in adulthood.

However, although most men with antisocial personality disorder had serious conduct-related problems as children (that is, they are reported to have exhibited symptoms of conduct disorder as children or teenagers), most boys with conduct problems do not go on to develop antisocial personality disorder (Hill, 2003; Maugham & Rutter, 2001). As shown in Figure 13.5, though, the more symptoms of conduct disorder a boy has, the more likely it is that he will develop antisocial personality disorder in young adulthood.

Most women with antisocial personality disorder did not have serious conduct problems when they were younger (Burnette & Newman, 2005). Even without meeting the diagnostic criteria for conduct disorder, however, girls who show a pattern of interpersonal and physical aggression are more likely to develop antisocial personality disorder as women. Although Reiland had conduct problems as a girl and as an adult she displayed some elements of antisocial personality disorder—impulsivity and irritability—she did not exhibit enough symptoms to meet the diagnostic criteria for this disorder.

Another risk factor that may lead conduct disorder to progress to antisocial personality disorder is socioeconomic status (SES): People with conduct disorder from lower SES groups have an increased risk of developing antisocial personality disorder (Lahey, Loeber et al., 2005).

Psychopathy: Is It Different Than Antisocial Personality Disorder?

The term *psychopath* (or *sociopath*, which was used in the first DSM) has often been used to refer to someone with symptoms of antisocial personality disorder. These two terms are not exactly the same, however. As illustrated in Figure 13.6, the

Figure 13.5

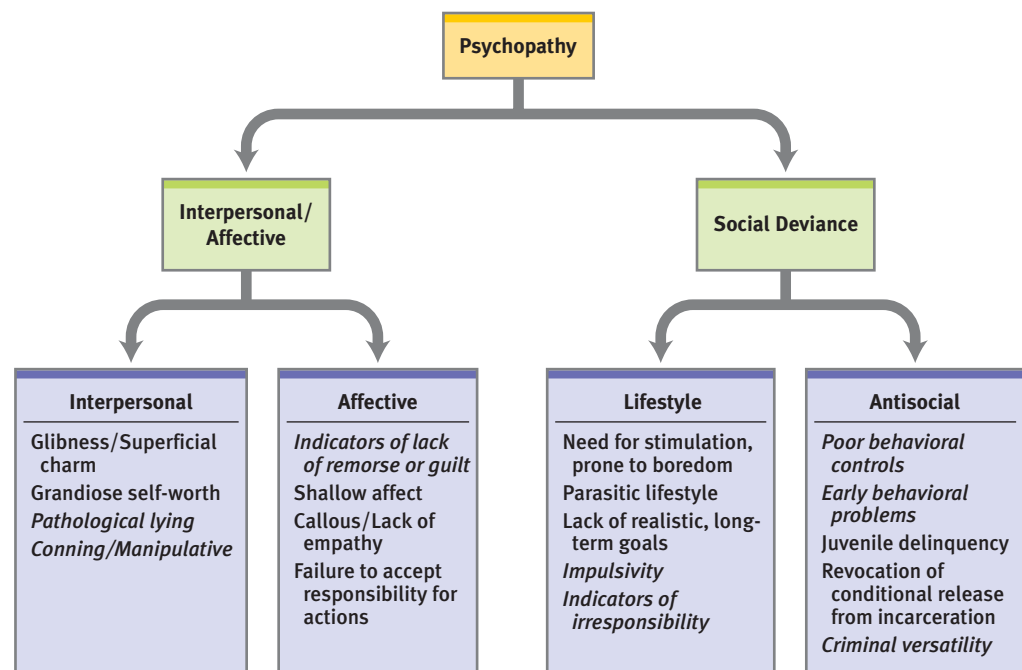

13.5 ▶ Conduct Disorder and Its Relation to Antisocial Personality Disorder

Boys 7–12 years old who have more symptoms of conduct disorder are more likely to develop antisocial personality disorder by age 19.

Figure 13.6

13.6 ▶ Symptoms of Psychopathy

The criteria for psychopathy are organized into two general groups, each of which has two clusters of criteria. The criteria for antisocial personality disorder (italicized) are much broader than those for psychopathy. For instance, most of the affective characteristics of psychopathy are not included in the criteria for antisocial personality disorder. The diagnosis of antisocial personality disorder is therefore likely to result in a more heterogeneous grouping than is psychopathy.

Source: Adapted from Hare, 2003. For more information see the Permissions section.

diagnosis of antisocial personality disorder is broader (i.e., less restrictive, because there are fewer criteria) than the diagnosis of psychopathy. Moreover, the diagnosis of antisocial personality disorder tends to focus more on *behaviors*—mostly criminal ones, such as stealing or breaking other laws—than on the personality traits that may underlie the behaviors. In contrast, **psychopathy** emphasizes specific emotional and interpersonal characteristics, such as a lack of empathy, an unmerited feeling of high self-worth, and a refusal to accept responsibility for one's actions—as well as antisocial behaviors. Psychopathy is generally considered to be a more universal concept than antisocial personality disorder; most cultures recognize a similar cluster of psychopathic characteristics (Cooke, 1998; Gacono et al., 2001).

Research findings reflect the relative breadth of the criteria for antisocial personality disorder compared to those for psychopathy: Although only a minority of prisoners (15% of male prisoners, 7.5% of female prisoners) meet the specific criteria for psychopathy, a majority of prisoners (50–80%) meet the broad behavioral criteria for antisocial personality disorder (Hare, 2003). And approximately 81% of people diagnosed with psychopathy also meet criteria for antisocial personality disorder, but only 38% of people diagnosed with antisocial personality disorder meet the criteria for psychopathy (Hart & Hare, 1989; Hildebrand & de Ruiter, 2004; Stålenheim & von Knorring, 1996; Sutker & Allain, 2001). In other words, although psychopathy and antisocial personality disorder have elements in common, psychopathy is defined more narrowly than antisocial personality disorder and with a different emphasis.

Understanding Antisocial Personality Disorder

The concept of psychopathy has been employed longer than the diagnosis of antisocial personality disorder. Hence, more research has addressed psychopathy and criminality than antisocial personality disorder—and the relative lack of research on antisocial personality disorder makes it difficult to identify the factors that contribute to the disorder (Ogloff, 2006). Moreover, most research that does examine factors that contribute to antisocial personality disorder has studied participants who are or have been in prisons or jails or who have comorbid substance abuse problems, which makes it difficult to sort out the factors that contribute solely to antisocial personality disorder. Therefore, the following sections examine neurological, psychological, and social factors—and the feedback loops among them—that contribute to antisocial personality disorder and/or psychopathy, keeping in mind the limitations of existing research.

Neurological Factors in Antisocial Personality Disorder and Psychopathy

People with antisocial personality disorder or psychopathy (and the groups have not been rigorously separated in most of this research) may have abnormal brain *structures* as well as abnormal brain *function* (Pridmore, Chambers, & McArthur, 2005). There is also evidence that these people are genetically biased to develop certain temperaments, which may contribute to their disorder.

Brain Systems First, regarding brain structure, people with antisocial personality disorder or psychopathy tend to have unusually small frontal lobes (Raine et al., 2000) and unusually small hippocampi (Laakso et al., 2001), but they have greater than normal amounts of white matter (the fatty insulation on axons, see Chapter 2) in the corpus callosum (the fibers that form the primary connection between the two cerebral hemispheres; Raine et al., 2003). The smaller frontal lobes might suggest problems in inhibiting and planning behavior. It is tempting to suggest that the smaller hippocampus reflects the effects of stress (see the discussion of posttraumatic stress disorder in Chapter 7), but people with this personality disorder do not generally perceive their situations as stressful, as other people would. Thus, it is not clear how to interpret this brain abnormality.

Second, regarding brain function, the frontal and temporal lobes of these patients tend to show less activation than normal—especially when the patients participate in tasks that involve classical conditioning (Schneider et al., 2000), tasks that require inhibiting responses (Smith, 2000; Völlm et al., 2004), and tasks that

Although the concepts of psychopathy and antisocial personality disorder overlap, they are not the same. Most prisoners meet the criteria for the diagnosis of antisocial personality disorder, but only 15% at most meet the criteria for psychopathy, which is defined more narrowly.

Thinkstock Images/Jupiterimages

Psychopathy

A set of emotional and interpersonal characteristics marked by a lack of empathy, an unmerited feeling of high self-worth, and a refusal to accept responsibility for one's actions.

require processing emotional pictures and words (Intrator et al., 1997; Kiehl et al., 2001). Moreover, these patients exhibit deficits on tasks that rely on the frontal lobes, such as those requiring planning or discovering that a rule has been changed (Dolan & Park, 2002). Such deficits probably contribute to their problems in inhibiting and planning behavior, and may also suggest that these people would have difficulty learning emotion-related information.

Neural Communication Antisocial personality disorder has been linked to genes that regulate dopamine production (Prichard et al., 2007) and also to genes that regulate serotonin (Lyons-Ruth et al., 2007). In fact, the dopamine and serotonin systems may not interact in normal ways in these patients. In one study, a novel drug that affects the balance of these systems (in complex ways) improved a range of psychological symptoms in patients with borderline personality disorder (Nickel et al., 2006)—such a study has yet to be conducted to examine antisocial personality disorder, but researchers speculate that the results would tell the same story.

Abnormal brain functioning may reflect or contribute to underlying differences in temperament. For instance, men diagnosed with antisocial personality disorder in adulthood were, at 3 years old, identified as distractible, impulsive, and restless (Caspi et al., 1996); these same qualities are observed in children with conduct disorder, which is to be expected, given the diagnostic criteria for antisocial personality disorder. However, these qualities are also evident in attention-deficit/hyperactivity disorder, which is not a precursor to the personality disorder (Satterfield, 1987).

Genetics As just noted, genes that affect dopamine and serotonin have been linked to this disorder, and these genes may influence temperament; thus, it is interesting that people with antisocial personality disorder consistently exhibit a number of specific temperament dimensions. One such dimension is high *reward dependence*—being highly motivated by the possibility of reward (Gray, 1987). Another is low *harm avoidance*, which can be thought of as low anxiety or as not being strongly motivated by the threat of punishment (Cloninger, 1987; Cloninger, Svrakic, & Przybeck, 1993; Gray, 1987; Lykken, 1995). A third temperament dimension shared by these people is low *persistence*—low frustration tolerance—which often leads to impulsive behavior and a tendency to take shortcuts.

And, in fact, researchers have reported evidence that genes contribute to these distinctive temperament dimensions (Zuckerman, 1991). Although few genetic studies focus on antisocial personality disorder specifically, what studies there are generally reveal that genetic factors bias a person to develop conduct disorder and criminality (Cadoret et al., 1995; Nigg & Goldsmith, 1994; Slutske et al., 1997). Adoption studies have found that the environment in which a child is raised influences the risk of criminal behavior or antisocial personality disorder only if the child is biologically vulnerable, as shown in Table 13.13. When a child's biological parents were not criminals, the child's later criminal behavior was unaffected by environmental influences, such as the number of foster placements before adoption or the adoptive parents' criminality (Caspi et al., 2002; Mednick, Gabrielli, & Hutchings, 1984).

Table 13.13 ▶ Percentage of Children Who Later Committed Crimes: The Role of Biology and Family Environment in Criminality

Exposure to Environmental Forces Associated with Criminality	Biological Parents' Criminality	
	High	Low
High	40.0%	6.7%
Low	12.1%	2.9%

Note: Environmental forces associated with criminality include variables such as the number of foster placements before adoption and the adoptive father's socioeconomic status.

Psychological Factors in Antisocial Personality Disorder and Psychopathy

Antisocial personality disorder and psychopathy appear to arise, in part, because of problems with classical and operant conditioning processes. These processes normally help to socialize children into law-abiding citizens who learn from their mistakes and who develop the ability to empathize with others. Instead, people with antisocial personality disorder view others as “marks” and look for opportunities to exploit them (Beck, Freeman, & Davis, 2004).

Whereas classical conditioning and operant conditioning lead most people to learn to avoid encounters with a painful stimulus (such as a shock), criminals with psychopathic traits do not learn to avoid painful stimuli—but when such criminals are given medication to increase the activity of their sympathetic nervous system, they *do* learn to avoid shocks at the same rate as control participants (Schachter & Latane, 1964). Thus, when not medicated, they cannot easily learn from punishing experiences (Eysenck, 1957) and are likely to repeat behavior associated with a negative consequence, despite receiving punishment (such as a prison sentence; Zuckerman, 1999). Moreover, their temperament of low harm avoidance means that they are less likely to be afraid of the threat of punishment. And because they are highly motivated by rewarding activities, they are less inclined to inhibit themselves to avoid punishment; they thus behave in ways that are impulsive, have difficulty delaying gratification, and have poor judgment (Silverstein, 2007).

Social Factors in Antisocial Personality Disorder and Psychopathy

One risk factor for conduct disorder and subsequent antisocial personality disorder is a child’s relationship with his or her parents or primary caretakers. Each parent or other primary caretaker has a style of interacting with the child from infancy. Some parents abuse or neglect their children or are inconsistent in disciplining them, which can lead to an insecure attachment (Bowlby, 1969). These children have a relatively high risk of developing conduct disorder and later antisocial personality disorder (Levy & Orlans, 1999, 2000; Ogloff, 2006). Note, however, that this finding is simply a correlation and does not necessarily mean that attachment difficulties *cause* later antisocial behavior; it is possible that some other variable makes it difficult for the children to develop normal attachment *and* more likely to develop antisocial behaviors.

Other childhood factors associated with the later development of antisocial personality disorder include poverty, family instability, and—in those who are genetically vulnerable—adoptive parents’ criminality (Raine et al, 1996).

FEEDBACK LOOPS IN ACTION: Antisocial Personality Disorder and Psychopathy

The various factors create feedback loops that ultimately produce psychopathy or antisocial personality disorder (see Figure 13.7). Twin and adoption studies reveal that some people have a predisposition toward criminality or associated temperaments (neurological factor), but the environment in which children grow up (social factor) influences whether that predisposition is likely to lead to criminal behavior. One study found that children with conduct disorder who were punished for their offenses were less likely to develop antisocial personality disorder later in life, confirming the contribution of operant conditioning to the disorder (Black, 2001).

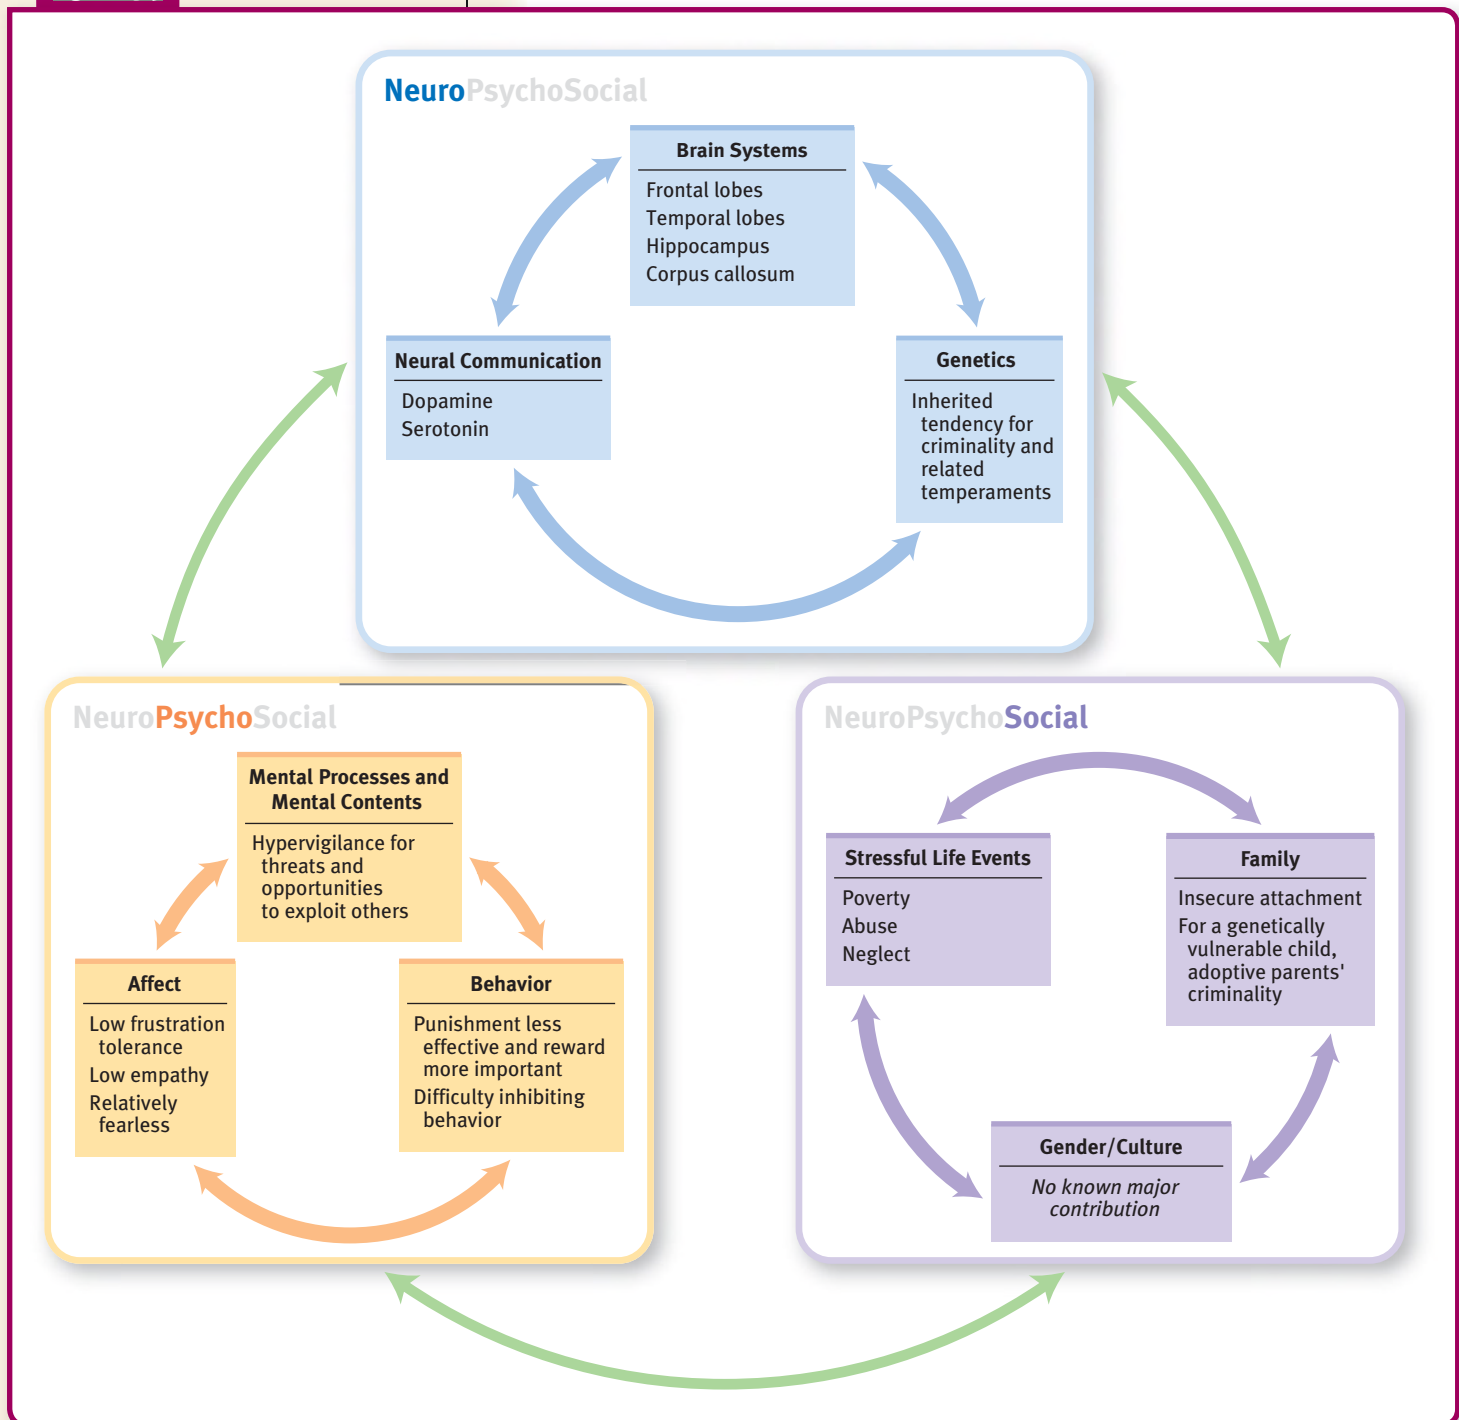

Moreover, the types of temperaments that are associated with antisocial personality disorder and psychopathy can impede the normal classical and operant conditioning processes that promote empathy and discourage antisocial behaviors (psychological factor; Kagan & Reid, 1986; Martens, 2005; Pollock et al., 1990). Finally, the experience of abuse or neglect by parents (social factor) may contribute to a tendency toward underarousal (Schorre, 2003), which in turn leads people to seek out more arousing (and reckless) activities that may increase their risk of seeing or experiencing violence (Jang, Vernon, & Livesley, 2001)—which they may find stimulating, and hence which may reinforce such behavior (making it more likely to occur in the future).

Treating Antisocial Personality Disorder and Psychopathy

Medication is usually prescribed to people with antisocial personality disorder or psychopathy only for comorbid disorders such as depression or a substance-use disorder (Gacono et al., 2001). The psychosocial treatments offered to these people

Figure 13.7

13.7 ► Feedback Loops in Action: Antisocial Personality Disorder and Psychopathy

depend on the setting: Those who are less violent are more likely to be seen in outpatient settings; those who are more violent are seen in prisons and jails.

Most research on treatment involves people diagnosed with psychopathy, not antisocial personality disorder specifically. Some of the personality traits associated with psychopathy interfere with a therapeutic collaboration: problems in delaying gratification, lack of empathy, and low frustration tolerance. Psychopathy has a poor prognosis, and treatments developed thus far are not likely to alter behavior or reduce symptoms (Gacono et al., 2001; Rice, Harris, & Cormier, 1992; Serin, 1991). People with

psychopathy who are in prison are likely to commit additional crimes after their release (Ogloff, Wong, & Greenwood, 1990; Seto & Barbaree, 1999). When an individual with psychopathy is violent, *managing* the patient, rather than *treating* the patient's personality problems, may be the more realistic and appropriate goal (Ogloff, 2006).

People with antisocial personality disorder who are most likely to respond to treatment have a comorbid anxiety disorder, and this capacity for anxiety may suggest that such people are not psychopaths (Meloy, 1988). A challenge in treating people with antisocial personality disorder is their utter lack of motivation. Because they aren't disturbed by their behavior, they are rarely genuinely motivated to change, which makes any real collaboration between therapist and patient unlikely; patients often will attend therapy only when required to do so. Treatment generally focuses on changing overt behaviors (Farmer & Nelson-Gray, 2005).

Treatments for people with antisocial personality disorder who are not psychopathic have some success—at least in the short term. These treatments focus on comorbid substance abuse and aggressive behavior (Henning & Frueh, 1996). The most effective treatments provide clear rules about behavior (including clear and consistent consequences for rule violations) and target behavior change and behavioral control, as is addressed with CBT. Such treatment programs teach patients to recognize triggers for problematic behaviors, devise more adaptive solutions, and foster impulse control (Fabiano, Robinson, & Porporino, 1990; MacKenzie, 2001). In contrast, treatments that target emotional and social factors, such as empathy training or social skills training, are less effective (Gacono et al., 2001).

Treatments that target social factors include family therapy aimed at decreasing inadvertent support from family members for antisocial behavior. These social treatments teach the patient and family members new ways of interacting (Gacono et al., 2001). In jail (or as a court-mandated alternative to jail time), some people may participate in *therapeutic communities*, 24-hour programs that tightly control the patient's behavior; some therapeutic communities are situated in prisons or jails. Research indicates that therapeutic communities can be effective for people who have both antisocial personality disorder and substance abuse (McKendrick et al., 2007; Woodall et al., 2007).

In sum, there is little research on treatments for antisocial personality disorder in people who do not also have comorbid substance use disorders. Treatment is usually court-ordered, and its effectiveness depends on whether the individual also has psychopathy or other psychological problems, and hinges in large part on his or her motivation to change.

Borderline Personality Disorder

The term “**borderline personality**” originally was used by psychodynamic therapists to describe patients whose personality was on the border between neurosis and psychosis (Kernberg, 1967). Now, however, it is generally used to describe the DSM-IV-TR personality disorder that includes some features of that type of personality: **borderline personality disorder**, which is characterized by volatile emotions, an unstable self-image, and impulsive behavior in relationships (American Psychiatric Association, 2000). The diagnostic criteria for borderline personality disorder are noted in Table 13.14. A key criterion is emotional dysregulation (also known as affective instability, Criterion 6), which leads the individual frequently to respond more emotionally than a situation warrants and to display quickly changing emotions (Glenn & Klonsky, 2009). Another prominent criterion refers to a relationship pattern of idealizing the other person at the beginning of the relationship, spending a lot of time with the person and revealing much, thus creating an intense intimacy. But then positive feelings quickly switch to negative ones, which leads the individual with this disorder to devalue the other person (Criterion 2). Rachel Reiland's pattern of thoughts, feelings, and behaviors meet the criteria for borderline personality disorder. Reiland describes the switch in how she viewed other people:

I saw people as either good or evil. When they were “good,” I vaulted them to the top of a pedestal. They could do no wrong, and I loved them with all of my being. When they were “bad,” they became objects of scorn and revenge.

Borderline personality disorder

A personality disorder characterized by volatile emotions, an unstable self-image, and impulsive behavior in relationships.

Table 13.14 ▶ DSM-IV-TR Diagnostic Criteria for Borderline Personality Disorder

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) **frantic efforts to avoid real or imagined abandonment.** Note: Do not include suicidal or self-mutilating behavior covered in Criterion 5.
- (2) **a pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.**
- (3) **identity disturbance: markedly and persistently unstable self-image or sense of self.**
- (4) **impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating).** Note: This impulsivity does not include suicidal or self-mutilating behavior covered in Criterion 5.
- (5) **recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.**
- (6) **affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria [poor mood], irritability, or anxiety usually lasting a few hours and only rarely more than a few days).**
- (7) **chronic feelings of emptiness.**
- (8) **inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).**
- (9) **transient, stress-related paranoid ideation or severe dissociative symptoms.**

Note: The criteria for borderline personality disorder involves four domains: Interpersonal (in green); cognitive (in orange); behavior (in purple); and emotional (in blue).

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

In relationships with those closest to me, the “good” and “bad” assessments could alternate wildly, sometimes from one hour to the next. The unrealistic expectations of perfection that came with the good-guy pedestal were destined to be unfulfilled, which led to disappointment and sense of betrayal.

(2004, p. 88)

The highly fluid and impulsive behaviors that are part of borderline personality disorder arise, in part, because of the patient’s strong responses to emotional stimuli. For example, if a patient with borderline personality disorder has to wait for someone who is late for an appointment, the patient often cannot regulate the ensuing powerful feelings of anger, anxiety, or despair, which can last for days. Moreover, the person with this personality disorder is extremely sensitive to any hint of being abandoned, which also can cause strong emotions that are then difficult to bring under control.

When not in the throes of intense emotions, people with borderline personality disorder may feel chronically empty, lonely, and isolated (Klonsky, 2008). When feeling empty, they may harm themselves in some nonlethal way—such as superficial cutting of skin—in order to feel “something”; such behavior has been called *parasuicidal* rather than suicidal because the intention is *not* to commit suicide, but rather to gain relief from feeling emotionally numb. The parasuicidal behavior usually occurs when the person is in a dissociated state, often after he or she has felt rejected or abandoned (Livesley, 2001). More worrying to clinicians, family members, and friends is when the self-harming behavior is a suicide attempt. In fact, almost 10% of people with borderline personality disorder die by suicide (Linehan & Heard, 1999; Paris, 1993).

Table 13.15 provides additional facts about borderline personality disorder. The table notes that this disorder is more commonly diagnosed in women than in men, but this difference may be due to diagnostic bias on the part of clinicians: Given identical cases and symptoms, clinicians are more likely to diagnose women with borderline personality disorder than men; clinicians may see women with symptoms of borderline personality disorder as more ill than their male counterparts (Becker & Lamb, 1994; Strain, 2003).

Lauren Shear/Photo Researchers

People with borderline personality disorder may engage in parasuicidal behaviors, such as cutting their arms, to help regulate their emotions. These scars on a 50-year-old woman are a result of such parasuicidal behavior. Self-harming behavior may also occur in an attempt to commit suicide.

Table 13.15 ► Borderline Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Borderline personality disorder occurs in 2% of the general population, 10% of outpatients, and 20% of inpatients. Among the personality disorders, borderline personality disorder is the most common: 30–60% of those diagnosed with a personality disorder have borderline personality disorder (Adams, Bernat, & Luscher, 2001; Widiger & Frances, 1989; Widiger & Trull, 1993). Borderline personality disorder is five times more common among first-degree relatives of someone with the disorder than in the general population.
Comorbidity
<ul style="list-style-type: none"> Common comorbid disorders include mood disorders, substance-related disorders, eating disorders (especially bulimia), and anxiety disorders (Grilo et al., 2004; Gunderson, Weinberg, et al., 2006; Zanarini et al., 2004).
Onset
<ul style="list-style-type: none"> As with all personality disorders, symptoms for borderline personality disorder emerge in childhood or adolescence.
Course
<ul style="list-style-type: none"> There is a high suicide rate among people with borderline personality disorder, with almost 10% dying by suicide (Linehan & Heard, 1999; Paris, 1993). The early adulthood years of people with this disorder are marked by mood episodes and serious impulse control problems, including suicide attempts; the risk of suicide peaks during early adulthood. Those who survive into their 20s and 30s are likely to improve within 10 years (Paris & Zweig-Frank, 2001; Zanarini, Frankenburg, Hennen, et al., 2006; Zanarini et al., 2007). Not all people improve, however (Skodol, Gunderson, et al., 2005). Those patients who meet fewer of the diagnostic criteria and who don't have a history of childhood trauma have a better prognosis 2 years after diagnosis (Gunderson, Daversa, et al., 2006).
Gender Differences
<ul style="list-style-type: none"> Around 75% of those diagnosed with borderline personality disorder are female.
Cultural Differences
<ul style="list-style-type: none"> The diagnostic criteria for borderline personality disorder—and its conceptual underpinnings—may not apply equally well in all cultures, especially Asian cultures (Lee, 2008).
Source: Unless otherwise noted, citations should be for American Psychiatric Association, 2000.

People with borderline personality disorder may have comorbid depression, as this individual does:

Thoughts of the past are prominent in my head. Bad person, naughty baby, no wonder my birth mother didn't want me. I'm not deserving of anything good in my life. I need to be punished just because I'm alive. Mind swirling, too many thoughts at once, can't cope. Worthless, burden, angry. The anger is initially directed at the right people. However, it doesn't stay there for long. I soon turn it around and, consequently, the anger returns to me, as it should do, because that's my lot in life. I should be used to it by now. Once more a failure.

(Castillo, 2003, p. 120)

Comorbid depression frequently contributes to increased suicidal thoughts, plans, or attempts. As borderline personality disorder symptoms diminish—including a decrease in emotional sensitivity—depression is likely to improve (Gunderson et al., 2004). Donna, in Case 13.6, exhibits extreme emotional sensitivity.

CASE 13.6 ► FROM THE OUTSIDE: Borderline Personality Disorder

[A woman, Donna, exhibited] episodes of explosive anger and bitter tirades, along with weekly (sometimes daily) expressions of bitterness and resentment. Frustrations and disappointments, which are inevitable within any relationship and would only be annoying

inconveniences to most people, were perceived by Donna as outrageous mistreatments or exploitations. Even when she recognized that they did not warrant a strong reaction, she still had tremendous difficulty stifling her feelings of anger and resentment. Her tendency to misperceive innocent remarks as being intentionally inconsiderate (at times even malevolent) further exacerbated her propensity to anger. She acknowledged that she would often push, question, and test her friends and lovers so hard for signs of disaffection, reassurances of affection, or admissions of guilt, that they would become frustrated and exasperated and might eventually lash out against her. She would often find herself embroiled in fruitless arguments that she subsequently regretted. She had no long-standing relationships, but there were numerous people who remained embittered toward her. Three marriages had, in fact, all ended in acrimonious divorce.

(Widiger, Costa, & McCrae, 2002, p. 443)

Distinguishing Between Borderline Personality Disorder and Other Disorders

Symptoms of borderline personality disorder overlap with symptoms of other psychological disorders. Borderline personality disorder and posttraumatic stress disorder, for instance, share the symptoms of dissociation, a feeling of numbness, and quickly shifting emotions. However, for people with borderline personality disorder, the most common emotion is anger; for people with posttraumatic stress disorder, it is fear or anxiety.

People with borderline personality disorder may occasionally have psychotic symptoms, such as hearing voices, but in contrast to people who have schizophrenia, they recognize that the voices are produced by their own minds and so they don't respond to them (Paris, 1999). Bipolar disorder and borderline personality disorder share the symptom of mood alteration. However, with borderline personality disorder, a mood change typically occurs over a period of hours, not weeks or months. Moreover, for people with borderline personality disorder, the mood changes come about in response to a clear trigger, such as feeling rejected or abandoned or disappointed by someone's behavior, as Reiland was when her husband didn't return home the moment she asked him to do so. Once triggered, the predominant unregulated emotion is anger (Paris, 1999).

Borderline personality disorder and antisocial personality disorder share the symptoms of impulsivity, instability in relationships, and manipulation of others. In general, people with borderline personality disorder manipulate others in order to meet emotional needs, whereas people with antisocial personality disorder manipulate others for personal gain. However, people can engage in both sorts of manipulation. In fact, up to 15% of people diagnosed with borderline personality disorder are also diagnosed with antisocial personality disorder (Grilo & McGlashan, 2005).

Understanding Borderline Personality Disorder

The neuropsychosocial approach allows us to appreciate the complexity of borderline personality disorder. In fact, this approach underlies the most comprehensive analysis that has been made of the disorder and its treatment (Linehan, 1993). Let's examine the elements of what Linehan (1993) calls the *biosocial theory* of borderline personality disorder and also consider research related to it.

Neurological Factors: Born to Be Wild?

Considerable research has been reported on the neurological bases of borderline personality disorder.

Brain Systems First, the frontal lobes, hippocampus, and amygdala are unusually small in people with borderline personality disorder (Driessen et al., 2000; Lyoo, Han, & Cho, 1998; Schmahl, Vermetten, et al., 2003; Tebartz van Elst et al., 2003). Second, these structures are part of a network of brain areas that functions abnormally in people with this disorder; this network includes the orbitofrontal and dorsolateral regions of the frontal lobe, the anterior cingulate, the amygdala,

and the hippocampus (De la Fuente et al., 1997; Juengling et al., 2003; Lieb et al., 2004; Soloff, Meltzer, et al., 2003).

Dysfunction of the anterior cingulate is particularly interesting because this structure plays a role in controlling affect: When normal control participants experience emotional and stressful situations, this area is activated; it is not activated in patients with borderline personality disorder (Schmahl, Elzinga, et al., 2003; Schmahl et al., 2004). This abnormality might contribute to the problems that people with this disorder have in regulating their emotions.

In contrast to the frontal lobes and the anterior cingulate, the amygdala (which is involved in the perception and production of strong emotions, notably fear) is *more* strongly activated than normal in these patients when they see faces with negative expressions (Donegan et al., 2003). This finding makes sense because the frontal lobes normally inhibit the amygdala (LeDoux, 1996); thus, if the frontal lobes are not working properly, they may fail to keep activation of the amygdala within a normal range.

In addition, consistent with findings from neuroimaging studies, numerous studies have shown that people who have borderline personality disorder have difficulty performing tasks that rely on the frontal lobes (LeGris & van Reekum, 2006). For example, they typically have difficulty inhibiting responses, such as is required in the Stroop task, where participants name the color of the ink (e.g., the word “red” is printed in blue ink) used to print the name of a color and the name conflicts with the color of the ink—and thus responses based on the name of the color must be inhibited (Kunert et al., 2003; Sprock et al., 2000). People with this disorder also have difficulty focusing attention, organizing visual material, and making decisions, and their visual and verbal memory is impaired (LeGris & van Reekum, 2006).

Neural Communication Relatively low levels of serotonin are related to impulsivity, which is characteristic of borderline personality disorder. Thus, it is not surprising that these patients have been shown to have abnormal serotonin functioning (Soloff et al., 2000); in particular, their serotonin receptors apparently are not as sensitive as normal, and thus the effects of serotonin are diminished (Hansenne et al., 2002). In addition, this dysfunction involving serotonin is apparently greater in women than in men with the disorder (Leyton et al., 2001; New et al., 2003; Soloff, Kelly et al., 2003)—and many more women than men receive this diagnosis.

But problems with serotonin alone cannot explain the abnormal brain functioning (Lieb et al., 2004). For instance, Rinne and colleagues (2002) showed that the hypothalamic-pituitary-adrenal (HPA) axis in at least some of these patients is unusually responsive, which results in excess amounts of cortisol.

The overall effect of these various brain abnormalities is consistent with Linehan’s theory. According to this theory, people with borderline personality disorder are likely to be neurologically vulnerable to emotional dysregulation. This vulnerability is usually expressed as a low threshold for emotional responding, with responses that are often extreme and intense. In addition, the brains of these people are relatively slow to return to a normal baseline of arousal.

Genetics Genetic studies do not find a specific transmission of borderline personality disorder itself (Torgersen et al., 2000). However, they do reveal a genetic vulnerability to components of this disorder, such as impulsivity, emotional volatility, and anxiety (Adams et al., 2001; Heim & Westen, 2005; Skodol, Siever, et al., 2002).

Psychological Factors: Emotions on a Yo-Yo

The core feature of borderline personality disorder is dysregulation—of emotion, of sense of self, of cognition, and of behavior (Robins, Ivanoff, & Linehan, 2001). For instance, people with this disorder feel unsure of themselves, of their goals and values; the one thing they are often sure of, however, is that they are in some way “bad” or “defective.” They may have been told repeatedly that they’re “too sensitive.” Their behaviors can be extreme: In one instant, they will fly into a rage over some inconsequential thing, but in the next instant, they will break down in tears and beg for reassurance, as Reiland did. These behaviors may inadvertently be reinforced by family members’ attention.

Other behaviors exhibited by people with this disorder—including substance use or abuse, binge eating, and parasuicidal behaviors—are more directly self-destructive and are often instigated with the goal of feeling better after interpersonal stress (Paris, 1999). Unfortunately, such maladaptive behaviors can be reinforcing because they *do* temporarily relieve emotional pain. Because of such temporary relief, these behaviors are negatively reinforced.

When highly emotionally aroused—by fear or anger, for instance—all of us are likely to have cognitive dysfunctions: difficulties in focusing attention and keeping long-term goals in mind, which makes impulsive urges more difficult to put in a larger context. Moreover, when in such an aroused state, people are more likely to distort or misinterpret what others say and do and to engage in black-and-white thinking, overlooking ambiguities or subtleties (Fonagy & Bateman, 2008). Both of these problems are more severe for people with borderline personality disorder. For example, when aroused, Reiland apparently did not pay attention to the actual cues her husband provided and would get so wrapped up in the emotions of the moment that she could not think about what was best for their relationship. And when aroused, Reiland interpreted her husband as not loving her, when all

he was doing was asking questions in order to understand the situation.

Social Factors: Invalidation

Borderline personality disorder also involves interpersonal dysregulation—relationships are typically intense, chaotic, and difficult (Robins, Ivanoff, & Linehan, 2001). One explanation for the interpersonal problems suggests that they arose in childhood—that family members and friends were likely to *invalidate* the patient's experience (Linehan, 1993). For instance, a parent might tell a child “You’re too sensitive” or “You’re overreacting.” During childhood, such dismissals may have led to fear of rejection and abandonment, if not actual rejection. Such experiences may have sensitized the child, leading him or her subsequently to overreact to the slightest hint of being invalidated.

In addition, this interpersonal dysregulation may arise in part because of patients' emotional and cognitive dysregulation (Fonagy & Bateman, 2008). When people with borderline personality disorder meet someone who is positive or helpful, they often begin by depending on that person to help calm their emotions, as Reiland did with her husband. But, paradoxically, once they feel dependent, they fear being abandoned—which leads them to behave in ways likely to lead to rejection! Friends and family members may come to respond with caring and concern only when the patient exhibits self-destructive behaviors (which, in turn, inadvertently reinforces those behaviors).

FEEDBACK LOOPS IN ACTION: Understanding Borderline Personality Disorder

Linehan's (1993) theory of borderline personality disorder rests on a series of feedback loops (like those illustrated in Figure 13.8): Some children have brain systems (neurological factor) that lead them to have extreme emotional reactions (psychological factor), and their parents may have difficulty soothing them (social factor) when they are emotionally aroused (Graybar & Boutelier, 2002; Linehan, 1993). Either because the parents create an invalidating environment (“It’s not as bad as you’re making it out to be”; social factor) or because they engage in outright abuse or neglect (as occurred with Reiland), the children may become insecurely attached to their parents. In turn, the children don’t learn to regulate their emotions or behaviors (and cognitions) and elicit untoward reactions from others, which then confirms their view of themselves and others.

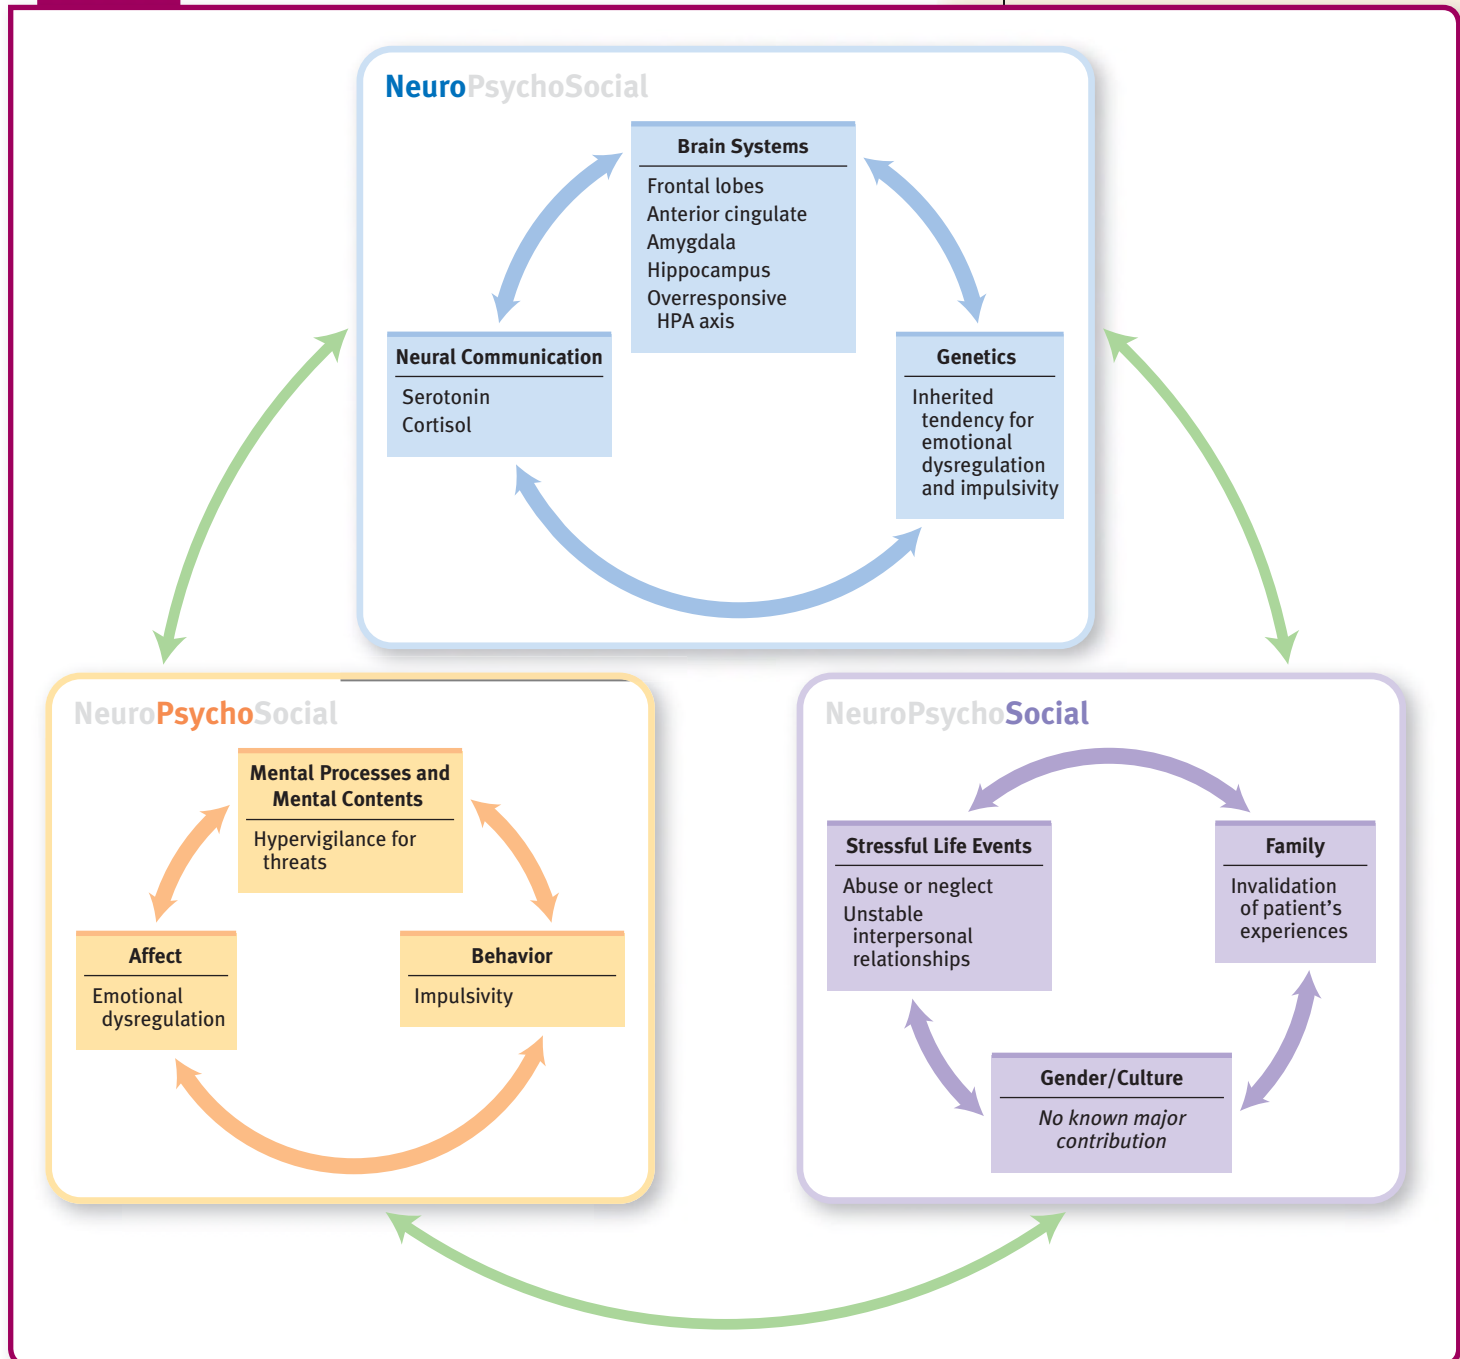

This invalidating process, according to Linehan, leaves the person feeling punished for his or her thoughts, feelings, and behaviors—they are trivialized, dismissed, disrespected (Linehan & Kehr, 1993). Such people therefore have a hard time identifying and labeling their emotions accurately and coming to trust their own experiences and perceptions as valid (psychological factor). They don’t learn effective problem solving or distress tolerance.

David Young-Wolff/Photo Edit

Although online message boards may provide support for adolescent girls and young women, they may also encourage or normalize the self-harming behavior that is associated with borderline personality disorder (Whitlock, Powers, & Eckenrode, 2006).

Figure 13.8

13.8 ► Feedback Loops in Action: Borderline Personality Disorder

Treating Borderline Personality Disorder: New Treatments

Borderline personality disorder is among the most challenging personality disorders to treat (Robins, Ivanoff, & Linehan, 2001). In part, treatment is challenging because of the patient's parasuicidal or suicidal thoughts and behaviors. It can also be challenging because of the intense anger that a patient may direct at the mental health clinician. Let's examine the various targets of treatment—neurological factors, psychological factors, and social factors—paying particular attention to a comprehensive psychological treatment that is the treatment of choice: *dialectical behavior therapy*.

Targeting Neurological Factors: Medication

Various medications may be prescribed to people with borderline personality disorder for a comorbid Axis I disorder or to target certain symptoms, including quickly changing moods, anxiety, impulsive behavior, and psychotic symptoms (Lieb et al., 2004). A review of studies suggests that for people with borderline personality disorder, SSRIs—compared to a placebo—may diminish symptoms of emotional lability and anxiety and help with anger management. In addition, antipsychotics can alleviate psychotic symptoms, and mood stabilizers may help some symptoms (Binks et al., 2006a). Although medications may reduce the intensity of some symptoms, psychopharmacology should not be the only form of treatment for people with borderline personality disorder (Koenigsberg, Woo-Ming, & Siever, 2007).

Targeting Psychological Factors: Dialectical Behavior Therapy

Marsha Linehan, a pioneer in the treatment of borderline personality disorder, initially treated such patients with CBT, which focuses on identifying and correcting faulty beliefs (Linehan, 1993; Beck et al., 2003). Unfortunately, this led some people to drop out of treatment because they felt that the focus on changing faulty beliefs implicitly criticized and invalidated them (Dimeff & Linehan, 2001). Linehan (1993) developed a new treatment for people with borderline personality disorder. From CBT she incorporated skill development and cognitive restructuring. In addition, in her new therapy she underscored the importance of a warm and collaborative bond between patient and therapist; to this mix she added the following elements:

- *An emphasis on validating the patient's experience.* That is, the patient's thoughts, feelings, and behaviors in a given situation make sense in the context of his or her life, past experiences, and strengths and weaknesses.
- *A Zen Buddhist approach.* Patients should see, and then without judgment, accept any painful realities of their lives. Patients are encouraged to “let go” of emotional attachments that cause them suffering. Mindfulness, or nonjudgmental awareness, is the goal.
- *A dialectics component.* *Dialectics* refers to a synthesis of opposing elements; in this context, it refers to the patient's coming to accept the situation and aspects of it that he or she does not feel able to change (e.g., validating his or her experience) while at the same time recognizing that in order to feel better, change must occur (Robins, Ivanoff, & Linehan, 2001).

Linehan called this treatment *dialectical behavior therapy* (DBT), and it entails both group and individual therapy. The initial priority of DBT is to reduce self-harming behaviors such as burning or cutting oneself. As these behaviors are reduced, treatment focuses on other behaviors that interfere with therapy and with the quality of life, and also helps patients develop skills to change what can be changed (e.g., their own behavior rather than the behavior of other people such as family members). In addition, treatment helps patients to recognize aspects of their lives that they can't change: For instance, although patients can learn to change the way they behave toward their parents, they can't change the way their parents behave toward them. Treatment lasts about 1 year.

Researchers have conducted many studies to evaluate DBT over the years and have noted impressive results for patients with borderline personality disorder: DBT does decrease suicidal thoughts and behaviors (Binks et al., 2006b; Bohus et al., 2000, 2004; Linehan et al., 2006; Shearin & Linehan, 1994) and has lower dropout and hospitalization rates than other specialized treatments for this disorder (Linehan et al., 2006). DBT benefits people with borderline personality disorder and comorbid substance abuse (Linehan et al., 1999; van den Bosch et al., 2005), and it has been adapted to treat people with Axis I disorders that involve impulsive symptoms, such as bulimia (Palmer et al., 2003; Telch, Agras, & Linehan, 2001).

Intensive (and manual-based) forms of psychodynamically oriented psychotherapy have also been shown to be effective for patients with borderline personality disorder (Bateman & Fonagy, 2004; Clarkin et al., 2007; Gregory & Remen, 2008).

Similarly, research indicates that cognitive therapy can be effective (Brown et al., 2004; Davidson et al., 2006; Wenzel et al., 2006).

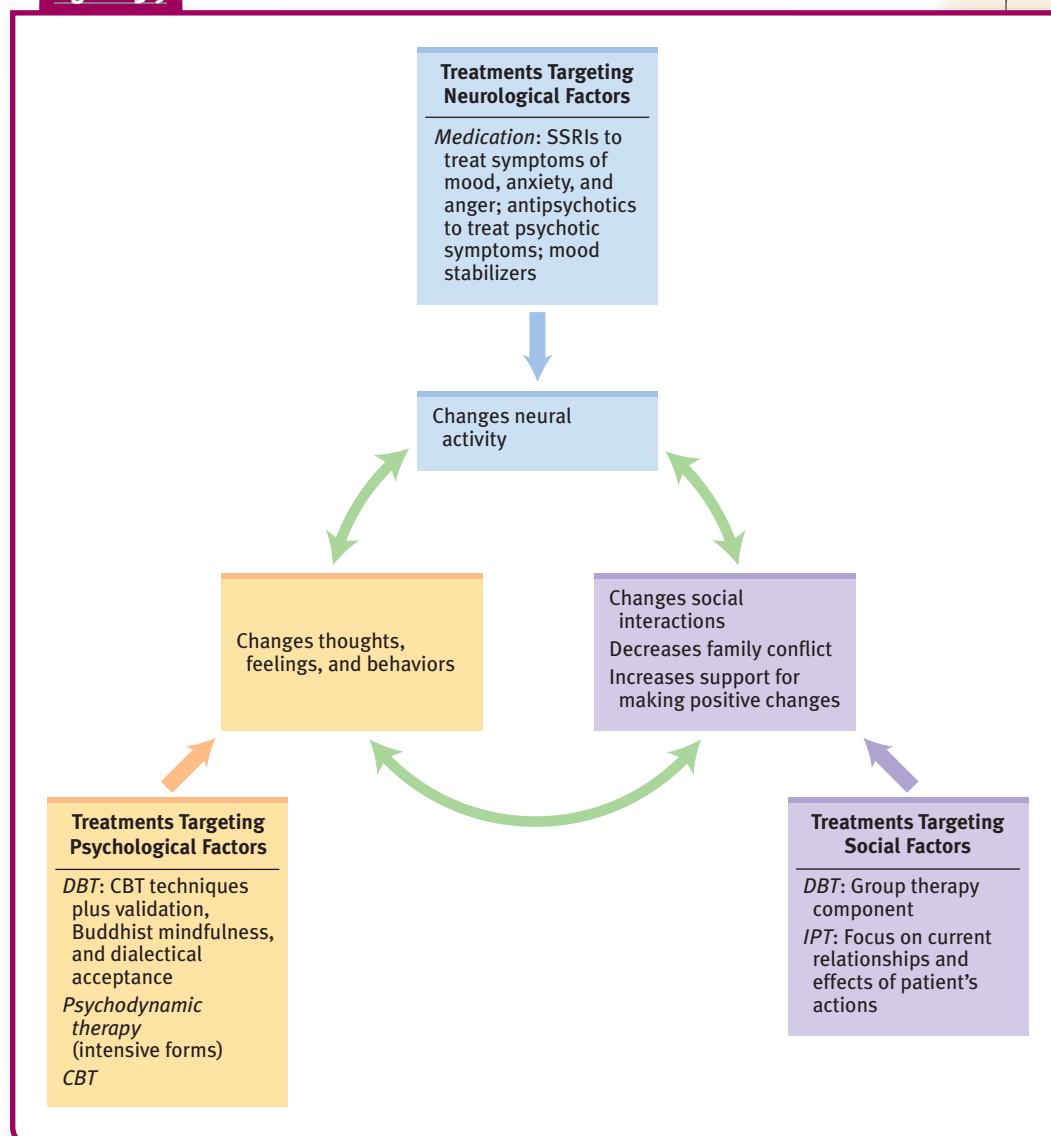

Targeting Social Factors: Interpersonal Therapy

Interpersonal therapy (IPT) has been adapted to treat borderline personality disorder. The goal of IPT for this personality disorder is to help the patient develop more adaptive interpersonal skills so that he or she feels and functions better. This therapy tries to help patients integrate their extreme but opposed feelings about an individual: When they talk about feeling one way about someone (“He’s perfect”), the therapist tries to discuss opposite feelings as well, underscoring that no individual is all good or all bad (Markowitz, 2005; Markowitz, Skodol, & Bleiberg, 2006). A course of IPT for borderline personality disorder typically lasts about 8 months. Social interactions are also a focus of the group therapy component of DBT.

FEEDBACK LOOPS IN TREATMENT: Borderline Personality Disorder

Successful treatment of borderline personality disorder may target more than one factor; positive changes in any factor, though, affect other factors via feedback loops (see Figure 13.9). For example, one goal of DBT is to help patients regulate their emotions (psychological factor). When the therapy is successful, better emotional regulation allows patients to calm themselves more effectively when they are anxious

Figure 13.9

13.9 ► Feedback Loops in Treatment: Borderline Personality Disorder

or angry, which directly affects brain mechanisms (neurological factor) and in turn makes their relationships less volatile (social factors). Similarly, the honest and caring feedback from others within the therapeutic environment (part of DBT, IPT, and intensive psychodynamic therapy) challenges patients to alter their behaviors and ways of thinking about themselves and their relationships (psychological and social factors), which in turn decreases their emotional reactivity (neurological and psychological factors).

Histrionic Personality Disorder

You may know someone who initially seemed charming, open, enthusiastic—maybe even flirtatious. After a while, did he or she seem to go to great lengths to be the center of attention, behaving too dramatically? Did the person have temper tantrums, sobbing episodes, or other dramatic displays of emotion that appeared to turn on and off like a light switch? These are the qualities of people with **histrionic personality disorder**, who seek attention and exaggerate their emotions (American Psychiatric Association, 2000).

Rachel Reiland relates her desire to be the center of attention and the dramatic behaviors she engaged in to obtain that attention:

I wanted to be the entire focus of any person I was obsessed with. My incessant hunger for attention had been a part of my life for as long as I could remember. The burning heartache of emptiness obsessed me even when my peers had been taken with Barbie dolls and coloring books. I knew even then that these constant feelings were not normal. . . .

When the object of my longing—the teacher, the coach, the boss—was present in the room, I geared everything to that person. I contrived every word, action, inflection, and facial expression for him. *Does he see me laughing? Does he see how funny everybody thinks I am?*

(2004, pp. 335–336)

Reiland's behavior involved some features of histrionic personality disorder; in what follows we examine the disorder in more detail.

What Is Histrionic Personality Disorder?

Table 13.16 lists the specific diagnostic criteria for histrionic personality disorder. Beyond the overt attention seeking and dramatic behavior, people with histrionic personality disorder may exhibit more subtle indications of the disorder: When they feel bored or empty, they seek out novelty and excitement. They may have difficulty delaying gratification and tend to become easily and excessively frustrated by life's challenges. Being in long-term relationships with people with histrionic personality

Table 13.16 ▶ DSM-IV-TR Diagnostic Criteria for Histrionic Personality Disorder

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) is uncomfortable in situations in which he or she is not the center of attention
- (2) interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
- (3) displays rapidly shifting and shallow expression of emotions
- (4) consistently uses physical appearance to draw attention to self
- (5) has a style of speech that is excessively impressionistic and lacking in detail
- (6) shows self-dramatization, theatricality, and exaggerated expression of emotion
- (7) is suggestible, i.e., easily influenced by others or circumstances
- (8) considers relationships to be more intimate than they actually are.

Histrionic personality disorder

A personality disorder characterized by attention-seeking behaviors and exaggerated and dramatic displays of emotion.

disorder can be challenging because they usually don't recognize their symptoms; they don't feel as though they are overreacting or being overly dramatic or seductive, although—like the woman in Case 13.7—they clearly are. Table 13.17 provides additional facts about the personality disorder.

CASE 13.7 ► FROM THE OUTSIDE: Histrionic Personality Disorder

A 23-year-old single woman was referred for a psychological assessment by her gynecologist. The patient had been described as “outgoing, effusive, and ‘dressed to kill’.”

She had been experiencing debilitating pain for over half a year, but the pain seemed to be medically unexplainable. Throughout the interview, she used facial and other nonverbal expressiveness to dramatize the meaning of her words. In describing her pain, for example, she said she felt as though “I will absolutely expire” as she closed her eyes and dropped her head forward to feign death. However, when asked about her pain, she became coquettish and was either unable or unwilling to provide details. She talked freely about topics tangential to the interview, skipping quickly from topic to topic and periodically inserting sexual double entendres. She described her family as happy and well-adjusted but acknowledged conflict with her mother and complained that her older brothers treated her like a baby. She described herself as close to her parents and said that she calls home every day. She was not currently in a serious relationship, but stated with a giggle that most boys “find me very attractive,” adding that they “just want me for my body.” She also reported that she found it easy to get to know others. At the time of the interview, she was working as a dancer at an adult club; she particularly liked the attention and the money that the job provided. She felt that, in contrast to the other girls, she was an artist. Her family believed that she was teaching ballet.

(Millon & Davis, 2000, p. 237; quoted in Horowitz, 2004, pp. 190–191)

Distinguishing Between Histrionic Personality Disorder and Other Disorders

Although people with antisocial personality disorder, borderline personality disorder, and histrionic personality disorder are all manipulative and impulsive, their motivations differ: People with histrionic personality disorder desire attention; people with antisocial personality disorder seek power or material gain; and people with borderline personality disorder want nurturance (Skodol, 2005). Moreover, although both histrionic and borderline personality disorders involve rapidly shifting emotions, only with the latter are the emotions usually related to anger.

Reiland's behavior fit some of the criteria for histrionic personality disorder, in that some of her dramatic displays seemed to be motivated by a desire for attention. She might be diagnosed with histrionic personality disorder as a comorbid disorder; however, the elements of her behavior that indicate borderline personality disorder overshadow the features of histrionic personality disorder. A clinician trying to make a definitive diagnosis (or diagnoses) would want to find out more about any thoughts, feelings, or behaviors that might indicate or rule out histrionic personality disorder.

Understanding Histrionic Personality Disorder

Unfortunately, little formal research has been conducted on histrionic personality disorder, but clinical observations have led to theories about how this disorder arises. Various psychological and social factors are theorized to contribute to the disorder. First, patients with this disorder are thought to believe themselves to be special, view other people as potential admirers, and apparently are sensitive to negative evaluation (Farmer & Nelson-Gray, 2005),

Table 13.17 ► Histrionic Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Approximately 2–3% of the general population will have histrionic personality disorder at some point during their lives (American Psychiatric Association, 2000; Grant, Hasin et al., 2004). Among people seeking treatment in inpatient and outpatient mental health settings, the prevalence of this disorder is 10–15%.
Comorbidity
<ul style="list-style-type: none"> Common comorbid Axis I disorders are somatoform disorders and major depressive disorder. Common comorbid Axis II disorders are borderline, narcissistic, antisocial, and dependent personality disorders (Skodol, 2005).
Onset
<ul style="list-style-type: none"> As with other personality disorders, symptoms must emerge by young adulthood.
Course
<ul style="list-style-type: none"> Symptoms of histrionic personality disorder typically improve over time (Seivewright, Tyrer, & Johnson, 2002).
Gender Differences
<ul style="list-style-type: none"> Some studies find histrionic personality disorder to occur as frequently in men as in women, but others find that it is diagnosed more frequently in women. Men with histrionic personality disorder may appear “macho” and seek attention for their athletic skills, not their appearance.
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

perhaps because of a temperament that is high in reward dependence. This personality disorder—in fact all four of the dramatic/erratic personality disorders—involve a sense of entitlement that drives the manipulative behavior (“I deserve this so I can do whatever it takes to get it”) and a poor tolerance of negative emotions (Beck, Freeman, & Davis, 2004). When frustrated or angry, people with histrionic personality disorder tend to have dramatic outbursts; others may, in turn, respond with attention, inadvertently reinforcing these outbursts (Farmer & Nelson-Gray, 2005).

Social factors that are thought to contribute to this disorder include the child-rearing practices of the parents. Specifically, one possibility is that people who develop histrionic personality disorder received significantly less attention than they desired during childhood; their subsequent inappropriate attempts (dramatic demands) to obtain attention were inadvertently reinforced, leading to a (maladaptive) belief that they must make an extraordinary effort to obtain attention (Kraus & Reynolds, 2001; Turner, 1994).

Treating Histrionic Personality Disorder

A goal of treatment for histrionic personality disorder is to help patients recognize and then modify their maladaptive beliefs and strategies (which are outlined in Table 13.20). Specifically, using techniques from CBT or psychodynamic therapy, the therapist tries to help patients increase their capacity to tolerate distress, develop more adaptive ways of responding to frustration, recognize the negative impact that their actions have on their relationships, and shift their view of themselves and other people (Beck, Freeman, & Davis, 2004; Farmer & Nelson-Gray, 2005). Like other patients with dramatic/erratic personality disorders, those with histrionic personality disorder often do not remain in treatment for long; they become bored or frustrated and continue to see other people as the primary problem.

Narcissistic Personality Disorder

People with **narcissistic personality disorder** have an inflated sense of their own importance, they expect—and demand—praise and admiration, and they lack empathy (American Psychiatric Association, 2000). This sense of self-importance, however, masks mixed feelings. On the one hand, they are preoccupied with their own concerns and expect others to be as well, and they get angry when other people don’t defer to them. They overvalue themselves and undervalue other people, which is true of Patricia in Case 13.8. On the other hand, their self-esteem can be fragile, leading them to fish for compliments. They are relatively insensitive to others’ feelings and points of view. Table 13.18 lists the diagnostic criteria for narcissistic personality disorder, and Table 13.19 presents additional information about this disorder.

CASE 13.8 ► FROM THE OUTSIDE: Narcissistic Personality Disorder

Patricia was a 41-year-old married woman who presented at an outpatient mental health clinic complaining of interpersonal difficulties at work and recurring bouts of depression. She described a series of jobs in which she had experienced considerable friction with coworkers, stating that people generally did not treat her with the respect she deserved. She attributed her depression to the recent suspicion that perhaps people did not like her because of her behavior. . . . Patricia reported a long history of banking jobs in which she had experienced interpersonal discord. Shortly before her entrance into treatment, Patricia was demoted from a supervisory capacity at her current job because of her inability to effectively interact with those she was supposed to supervise. She described herself as always feeling out of place with her coworkers and indicated that most of them failed to adequately appreciate her skill or the amount of time she put in at work. She reported that she was beginning to think that perhaps she had something to do with their apparent dislike of her. Patricia stated several times . . . that the tellers at the bank were jealous of her status and abilities as a loan officer and that this made them dislike her.

(Corbitt, 2002, pp. 294–295)

Narcissistic personality disorder

A personality disorder is characterized by an inflated sense of importance, an excessive desire to be admired, and a lack of empathy.

Table 13.18 ▶ DSM-IV-TR Diagnostic Criteria for Narcissistic Personality Disorder

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
- (2) is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
- (3) believes that he or she is “special” and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
- (4) requires excessive admiration
- (5) has a sense of entitlement, i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations
- (6) is interpersonally exploitative, i.e., takes advantage of others to achieve his or her own ends
- (7) lacks empathy: is unwilling to recognize or identify with the feelings and needs of others
- (8) is often envious of others or believes that others are envious of him or her
- (9) shows arrogant, haughty behaviors or attitudes

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

Note that Patricia, in Case 13.8, said that people didn’t treat her with the respect that she felt she deserved and that she didn’t feel adequately appreciated; people with narcissistic personality disorder often report such feelings. Although all of the dramatic/erratic personality disorders in Cluster B have criteria that involve callous and demanding behaviors, narcissistic personality disorder stands out for its features of grandiosity and a general *lack* of impulsivity or clear-cut self-destructive behaviors. In addition, people with narcissistic personality disorder fear abandonment less than do people with borderline personality disorder (Skodol, 2005).

Although Reiland had symptoms of each of the dramatic/erratic personality disorders, her symptoms do not meet the criteria for a diagnosis of narcissistic personality disorder; her problematic behaviors were often impulsive and self-destructive. Although her symptoms clearly met the criteria for borderline personality disorder, a clinician would need additional information to determine whether she had a comorbid dramatic/erratic personality disorder.

Understanding Narcissistic Personality Disorder

As is true for histrionic personality disorder, very little research has been conducted on narcissistic personality disorder, and so, again, we examine clinically based theories about how the disorder arises. The same psychological and social factors that are theorized to contribute to histrionic personality disorder are also theorized to contribute to narcissistic personality disorder. In fact, patients with these disorders share the belief that they are special and impressive, view other people as potential admirers, and are especially sensitive to negative evaluation (Farmer & Nelson-Gray, 2005). However, the two disorders are not the same: People with these disorders have distinct biases in their views of themselves versus others, tend to hold different maladaptive beliefs, and rely on different maladaptive strategies (see Table 13.20).

Table 13.19 ▶ Narcissistic Personality Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none">Approximately 1% of the general population will have narcissistic personality disorder at some point in their lifetimes.
Comorbidity
<ul style="list-style-type: none">Common Axis I comorbid disorders are substance-related disorders and anorexia nervosa.Common comorbid personality disorders include paranoid personality disorder and the other Cluster B (dramatic/erratic) personality disorders: histrionic, borderline, and antisocial personality disorders.
Onset
<ul style="list-style-type: none">As with other personality disorders, symptoms must emerge by early adulthood.
Course
<ul style="list-style-type: none">People with narcissistic personality disorder may have a hard time adjusting to physical or occupational limitations that arise with advancing age.People with this disorder may function at a lower level than they seem capable of, because they are unwilling to risk possible defeat.
Gender Differences
<ul style="list-style-type: none">Between 50% and 75% of those diagnosed with narcissistic personality disorder are male.
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

Table 13.20 ▶ Maladaptive Views, Beliefs, and Strategies of Individuals with Narcissistic and Histrionic Personality Disorders

Personality Disorder	View of Self	View of Others	Main Beliefs	Main Strategies (Overt Behavior)
Histrionic	Glamorous, impressive	Seducible, receptive, admiring	"I need to impress others." "People are there to serve and admire me." "People have no right to deny me my just desserts."	Dramatics, charm, temper tantrums, crying; suicidal gestures
Narcissistic	Special, unique; above the rules	Inferior, admiring	"I am special." "Since I'm special, I <i>deserve</i> special rules." "I'm better than others."	Self-aggrandize, use others; transcend rules; manipulate; compete

Source: Beck, Freeman, & Davis, 2004, pp. 21, 36, 48–49.

As for histrionic personality disorder, parents' child-rearing practices are thought to contribute to an adult's subsequent narcissistic personality disorder. However, one theory about how narcissistic personality disorder arises proposes that parents were too attentive and permissive, leading the child to have an overinflated sense of self-worth and to expect others to give him or her the same unqualified positive responses as did the parents (Millon, 1998).

Treating Narcissistic Personality Disorder

Treatment for narcissistic personality disorder is basically the same as treatment for histrionic disorder. Again, the therapist seeks to help patients recognize and then modify their maladaptive beliefs and strategies (as outlined in Table 13.20), using techniques of CBT or psychodynamic therapy. However, as for all patients with dramatic/erratic personality disorders, those with narcissistic personality disorder usually do not remain in treatment for long—and typically continue to see other people as the primary problem rather than their own beliefs or behaviors.

Key Concepts and Facts About Dramatic/Erratic Personality Disorders

- The hallmark of antisocial personality disorder is a persistent disregard for the rights of others, which may lead these people to violate rules or laws or to act aggressively. To be diagnosed with this personality disorder, an individual must have exhibited symptoms of conduct disorder before the age of 15.
- The diagnostic criteria for antisocial personality disorder overlap with aspects of psychopathy. However, psychopathy is defined by a more restrictive set of criteria, which focus on emotional and interpersonal characteristics, such as a lack of empathy, as well as antisocial behaviors. In contrast, the criteria for antisocial personality disorder tends to focus on behaviors, particularly criminal behaviors. More criminals are diagnosed with antisocial personality disorder than with psychopathy.
- Psychopathy and antisocial personality disorder are thought to arise from feedback loops among various factors, including genes and temperament, lack of empathy, classical and operant conditioning, abuse or neglect or inconsistent discipline in childhood, parents' criminal behavior, and attachment style. Treatment for psychopathy has generally not been successful; treatment for antisocial personality disorder focuses on modifying specific behaviors and has some degree of success, at least temporarily, in motivated individuals.
- Borderline personality disorder is characterized by volatile emotions, an unstable self-image, and impulsive behavior in relationships. People with this disorder have problems with emotional regulation—which is probably related to their temperament—and may engage in self-harming behaviors or try to commit suicide.
- Factors that contribute to borderline personality disorder include the genetic and neurological underpinnings of emotional dysregulation, a relatively low threshold for emotional responsiveness, an easily changeable sense of self, cognitive distortions, and a history of abuse, neglect, or feeling invalidated by others.
- Treatment for borderline personality may include medication, CBT, DBT, intensive psychodynamic therapy, and IPT.
- The hallmark of histrionic personality disorder is attention seeking, usually through exaggerated emotional displays. Symptoms may also include a sense of boredom or emptiness and a low tolerance for frustration.
- Narcissistic personality disorder is characterized by a grandiose sense of self-importance and a constant desire for praise and

admiration. People with this disorder may also feel a sense of entitlement, behave arrogantly, and have difficulty understanding other people's points of view.

- Histrionic and narcissistic personality disorders are theorized to arise from a combination of temperament, maladaptive beliefs and behaviors, and social interactions. Patients with these personality disorders often drop out of treatment early, in part because they are reluctant to shift from viewing others as the cause of their problems to viewing or acknowledging their own role in creating their problems.

Making a Diagnosis

- Reread Case 13.5 about John, and determine whether or not his symptoms meet the criteria for antisocial personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

- Reread Case 13.6 about Donna, and determine whether or not her symptoms meet the criteria for borderline personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 13.7 about the 23-year-old woman, and determine whether or not her symptoms meet the criteria for histrionic personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 13.8 about Patricia, and determine whether or not her symptoms meet the criteria for narcissistic personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Fearful/Anxious Personality Disorders

The personality disorders in Cluster C—avoidant, dependent, and obsessive-compulsive personality disorders—share the feature of anxiety or fear. Although they have this superficial commonality, there is little overlap among the diagnostic criteria for these three disorders; this is in sharp contrast to the disorders within Cluster A (odd/eccentric) and those within Cluster B (dramatic/erratic), which have overlapping criteria.

Avoidant Personality Disorder

The predominant characteristic of people with **avoidant personality disorder** is *social inhibition*—extreme shyness—that usually stems from feeling inadequate and being overly sensitive to negative evaluation (American Psychiatric Association, 2000). People with avoidant personality disorder are often characterized as shy, isolated, timid, or lonely.

What Is Avoidant Personality Disorder?

The diagnostic criteria for avoidant personality disorder (see Table 13.21) all relate to the individual's predominant concern about embarrassing himself or herself during social interactions—perhaps by blushing or crying—and being socially rejected or humiliated. These fears, in turn, lead the individual to try to limit social interactions.

People with avoidant personality disorder are so reluctant to engage in social interactions that they may turn down a promotion if the position requires increased social contact. And they are often hypervigilant for any indication of criticism or rejection. Unfortunately, their social fears and anxieties cause them to behave in tense and fearful ways—for example, not talking about themselves for fear of what others might think—when they

Avoidant personality disorder

A personality disorder characterized by extreme social inhibition (i.e., extreme shyness) that usually stems from feeling inadequate and being overly sensitive to negative evaluation.

Table 13.21 ▶ DSM-IV-TR Diagnostic Criteria for Avoidant Personality Disorder

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

- (1) avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection.
- (2) is unwilling to get involved with people unless certain of being liked.
- (3) shows restraint within intimate relationships because of the fear of being shamed or ridiculed.
- (4) is preoccupied with being criticized or rejected in social situations.
- (5) is inhibited in new interpersonal situations because of feelings of inadequacy.
- (6) views self as socially inept, personally unappealing, or inferior to others.
- (7) is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

Table 13.22 ▶ Avoidant Personality Disorder Facts at a Glance

Prevalence	
<ul style="list-style-type: none">• Approximately 0.5–2.5% of the general American population has avoidant personality disorder (American Psychiatric Association, 2000; Grant, Hasin, et al., 2004).• Up to 10% of those seen in outpatient clinics have this disorder.	
Comorbidity	
<ul style="list-style-type: none">• Common comorbid Axis I disorders are mood disorders or anxiety disorders.• Because the diagnostic criteria overlap with those of social phobia, comorbidity between the two disorders is very high (Shea et al., 2004; Skodol, 2005; Skodol et al., 1995); in one study, 43% of people diagnosed with social phobia were also diagnosed with avoidant personality disorder (Faravelli et al., 2000).• Common comorbid Axis II personality disorders are dependent personality disorder (because patients are dependent on the few friends they have), borderline personality disorder, and the Cluster A (odd/eccentric) personality disorders.	
Onset	
<ul style="list-style-type: none">• Based on the diagnostic criteria, symptoms such as shyness or a fear of strangers or new situations must emerge by early adulthood.	
Course	
<ul style="list-style-type: none">• Two years after diagnosis, approximately 50% of people with avoidant personality disorder improve enough with treatment that their symptoms no longer meet the criteria (Grilo et al., 2004).	
Gender Differences	
<ul style="list-style-type: none">• Men and women do not consistently differ in their prevalence rates for avoidant personality disorder (Torgersen, 2005).

do interact with other people. This anxious way of relating to others may inadvertently elicit a mild version of the very reaction they fear—that others will evaluate them in a negative light. Among all people with personality disorders, those with avoidant personality disorder report the lowest quality of life (Cramer, Torgersen, & Kringlen, 2003; Wilberg et al., 2009). Table 13.22 provides additional facts about this disorder, and Case 13.9 describes one individual's experience.

CASE 13.9 ▶ FROM THE OUTSIDE: Avoidant Personality Disorder

Marcus is a 33-year-old man who recently divorced.

His marriage deteriorated over several years and primarily as the result of his wife's increasing frustration with his unwillingness to do anything to improve his situation. He is employed as a warehouse manager and has held the same position for 9 years. He sees others doing more with their lives and wishes that he could as well. Although he hates that his wife chose to leave the marriage, he cannot blame her for doing so. Each evening after work he is filled with feelings of self-contempt and anguish. He would like to go out and be with other people, but he is certain that no one wants his company. He finds that drinking alcohol and watching television usually takes his mind off this unfulfilling life. Marcus thinks of committing suicide frequently.

(Rasmussen, 2005, p. 201)

Dependent personality disorder

A personality disorder characterized by submissive and clingy behaviors, based on fear of separation.

Distinguishing Between Avoidant Personality Disorder and Other Disorders

If you're thinking that you've read about a disorder that seems similar to avoidant personality disorder earlier in this textbook, you're correct. Avoidant personality disorder has much in common with social phobia (Chapter 7), and the symptoms

of the two disorders overlap (Chambless, Fydrich, & Rodebaugh, 2008; Tillfors et al., 2004). However, the criteria for avoidant personality disorder are broader than those for social phobia, and the symptoms include a more pervasive sense of inadequacy or inferiority and a reluctance to take risks (Skodol, 2005), as was true of Marcus in Case 13.9.

When making the diagnosis of avoidant personality disorder, clinicians must take cultural factors into account (American Psychiatric Association, 2000). For example, recent immigrants may exhibit symptoms of this disorder, perhaps because of language barriers or concerns about safety, and so clinicians must be sure to ask whether the behavior predates immigration. Similarly, ethnic and religious groups have different norms about appropriate levels of social contact and avoidance, and so clinicians should ascertain whether social norms, and not a true fear of social contact, drive the behaviors. For example, among deeply observant Muslims, the norm is for women to shun social contact with men who are not family members, and such behavior by a woman in this group should not be taken to indicate avoidant personality disorder. Because the three fearful/anxious personality disorders have not been studied in depth, we will discuss the underlying bases for and treatment of all three disorders after we consider specific features of each of them separately.

Dependent Personality Disorder

Dependent personality disorder is characterized by submissive and clingy behaviors, based on fear of separation. The DSM-IV-TR definition notes that the clingy behaviors are intended to elicit attention, reassurance, and decisive behaviors from other people (American Psychiatric Association, 2000). These behaviors are not a temporary bid for attention or reassurance (like the behaviors of those with borderline or histrionic personality disorder), but are part of a chronic pattern of helpless behavior.

What Is Dependent Personality Disorder?

People with dependent personality disorder are chronically plagued by self-doubt and consistently underestimate their abilities (see Table 13.23 for the list of diagnostic criteria). Thus, they have a hard time making all kinds of decisions, from life-altering ones about what career to pursue to mundane decisions about what clothes to wear. They prefer to have other people make such choices for them. And because they are so quick to believe they are wrong, they are likely to see any criticism or disapproval as proof of their basic negative beliefs about themselves.

People with dependent personality disorder often don't learn the skills needed to function independently and so are, in fact, dependent on others; they have reason to be concerned about living on their own. When a relationship ends, they typically leap into another one in order to ensure that they are not alone. Even while in an intimate relationship, they are often preoccupied with the possibility that the relationship will end and they will have to fend for themselves. Individuals with dependent personality disorder are

Patrick Ryan/Getty Images

Symptoms of avoidant personality disorder and social phobia overlap, and people with either disorder are excessively concerned about being rejected by others or behaving in a way that leads them to feel humiliated. However, the social difficulties and feelings of inadequacy of people with avoidant personality disorder are generally more pervasive than those of people with the Axis I disorder, and can make meetings like this extremely uncomfortable or even impossible.

Table 13.23 ▶ DSM-IV-TR Diagnostic Criteria for Dependent Personality Disorder

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) has difficulty making everyday decisions without an excessive amount of advice and reassurance from others.
- (2) needs others to assume responsibility for most major areas of his or her life.
- (3) has difficulty expressing disagreement with others because of fear of loss of support or approval. Note: Do not include realistic fears of retribution.
- (4) has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy).
- (5) goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant.
- (6) feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself.
- (7) urgently seeks another relationship as a source of care and support when a close relationship ends.
- (8) is unrealistically preoccupied with fears of being left to take care of himself or herself

**Table 13.24 ► Dependent Personality Disorder
Facts at a Glance****Prevalence**

- The prevalence of dependent personality disorder in the general population is less than 1% (Grant, Hasin, et al., 2004).

Comorbidity

- Common Axis I disorders are mood disorders and anxiety disorders.
- Common comorbid personality disorders are avoidant, borderline, and histrionic personality disorders.

Onset

- As required by the diagnostic criteria, symptoms must emerge by young adulthood.

Course

- Symptoms may improve over time, to the point where the individual no longer meets the criteria for the disorder (Markowitz et al., 2005).

Gender Differences

- In the general population, women tend to be diagnosed with dependent personality disorder more often than men (Torgersen, 2005); in a clinical setting, however, men and women may have similar prevalence rates (American Psychiatric Association, 2000).

Source: Unless otherwise noted, citations are to American Psychiatric Association, 2000.

most comfortable in relationships with people who take the initiative—and take responsibility. Not surprisingly, then, they often choose overprotective and dominating people to be their friends and partners, becoming passive in those relationships. Generally, people who have dependent personality disorder have a limited social circle, consisting of only a few people on whom they depend, as is true of Matthew in Case 13.10. Once they have established a relationship, people with dependent personality disorder are hesitant to disagree with the other person for fear that he or she will withdraw emotional support. In fact, an individual with this personality disorder may go to great lengths to maintain the extensive support that the other person provides, even tolerating mental or physical abuse (American Psychiatric Association, 2000).

It is important to note that even if an individual possesses enough of the characteristics to meet the diagnostic criteria in Table 13.23, he or she will not be diagnosed with dependent personality disorder unless these characteristics significantly impair functioning in major areas of life. Table 13.24 provides additional information about this disorder.

CASE 13.10 ► FROM THE OUTSIDE: Dependent Personality Disorder

Matthew is a 34-year-old single man who lives with his mother and works as an accountant. He is seeking treatment because he is very unhappy after having just broken up with his girlfriend. His mother had disapproved of his marriage plans, ostensibly because the woman was of a different religion. Matthew felt trapped and forced to choose between his mother and his girlfriend, and because “blood is thicker than water,” he had decided not to go against his mother’s wishes. . . . Matthew is afraid of disagreeing with his mother for fear that she will not be supportive of him and he will then have to fend for himself. He criticizes himself for being weak, but also admires his mother and respects her judgment. . . . He feels that his own judgment is poor.

Matthew works at a job several grades below what his education and talent would permit. On several occasions he has turned down promotions because he didn’t want the responsibility of having to supervise other people or make independent decisions. . . . He has two very close friends whom he has had since early childhood. He has lunch with one of them every single workday and feels lost if his friend is sick and misses a day.

Matthew is the youngest of four children and the only boy. . . . He had considerable separation anxiety as a child—he had difficulty falling asleep unless his mother stayed in the room, mild school refusal, and unbearable homesickness when he occasionally tried “sleepovers.” . . . He has lived at home his whole life except for 1 year of college, from which he returned because of homesickness.

(Spitzer, Gibbon, et al., 2002, pp. 179–180)

Distinguishing Between Dependent Personality Disorder and Other Disorders

Avoidant and dependent personality disorders share the characteristics of desire for reassurance, feelings of inadequacy, and submissive behaviors (Leising, Spörberg, & Rehbein, 2006). However, with avoidant personality disorder, these characteristics focus on feeling socially inept, whereas with dependent personality disorder, they focus on feeling incapable of taking care of oneself (Skodol, 2005), as Matthew in Case 13.10 felt.

When considering the diagnosis of dependent personality disorder, clinicians need to keep in mind that cultures have different norms about appropriate dependent behaviors; moreover, these norms may vary for men and women and for people of different ages. For instance, some Asian cultures may promote more deference or passivity than is the norm in North America, and some Latino cultures promote *marianismo* (the opposite of machismo), where women are expected to be submissive to and dependent on men. These behaviors, normal within those cultures, should be distinguished from symptoms of dependent personality disorder (Paniagua, 2001).

Obsessive-Compulsive Personality Disorder

Obsessive-compulsive personality disorder is characterized by preoccupations with perfectionism, orderliness, and self-control as well as low levels of flexibility and efficiency (American Psychiatric Association, 2000). It is the personality disorder associated with the least disability (Skodol, Gunderson, et al., 2002) and the highest obtained educational level (Torgersen, Kringlen, & Cramer, 2001). Rachel Reiland describes her father as having some elements of obsessive-compulsive personality disorder: He was strict, “coveted control,” and became enraged when events weren’t to his liking. Reiland herself had some elements of this disorder: “Once upon a time perfectionism was my noble aspiration. My perfectionism extended beyond academics or career. I also aspired to be the perfect mother, lover, and friend, always appropriate in all my emotional expressions” (2004, p. 361).

What Is Obsessive-Compulsive Personality Disorder?

People with obsessive-compulsive personality disorder can get so bogged down in details that they leave the most important elements to the last minute (see Table 13.25 for the complete diagnostic criteria). For instance, when preparing a presentation, people with this disorder might spend hours creating a single PowerPoint slide, trying to get it perfect, and end up running out of time for organizing their talk. They can’t see the forest for the trees. For people with obsessive-compulsive personality disorder, decision making is a painful, long process; thus, once they’ve made a decision, they’re not likely to change their minds—which can end up making them appear rigid and inflexible. And, like Reiland’s father, when they are unable to control a situation, they may become angry, irritable, or upset.

Some (but not all) people who are workaholics may have obsessive-compulsive personality disorder—they may feel uncomfortable on vacations unless they take work along with them. Alternatively, others with obsessive-compulsive personality disorder may spend inordinate amounts of time on hobbies or household chores, striving for perfection and adhering to rules inflexibly. They may hold others to these same unrealistically stringent standards.

The relationships of people with obsessive-compulsive personality disorder are normally formal and serious; they are preoccupied with logic and intellect, are overly conscientious, and are intolerant of emotional or “illogical” behavior in others. Typically, people with obsessive-compulsive personality disorder feel uncomfortable with others who express emotions easily and openly. People with this disorder are not likely to express tender feelings or pay compliments. Other people often feel frustrated by their rigidity. In turn, people with

Obsessive-compulsive personality disorder

A personality disorder characterized by preoccupations with perfectionism, orderliness, and self-control as well as low levels of flexibility and efficiency.

Table 13.25 ▶ DSM-IV-TR Diagnostic Criteria for Obsessive-Compulsive Personality Disorder

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

- (1) is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost
- (2) shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met)
- (3) is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity)
- (4) is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
- (5) is unable to discard worn-out or worthless objects even when they have no sentimental value
- (6) is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things
- (7) adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes
- (8) shows rigidity and stubbornness

Photodisc/Getty Images

Some workaholics have obsessive-compulsive personality disorder: They are perfectionistic and extremely orderly and organized. However, they can become so preoccupied with doing a job perfectly that they are inefficient or can't complete the task. Moreover, when problems arise, they can be rigid and inflexible.

obsessive-compulsive personality disorder have difficulty acknowledging the perspectives of others, as is true of Mr. V in Case 13.11. Table 13.26 provides additional information about this disorder.

CASE 13.11 ▶ FROM THE OUTSIDE: **Obsessive-Compulsive Personality Disorder**

Mr. V, a 25-year-old philosophy graduate student, began twice-weekly psychotherapy. His presenting complaint was difficulty with completing work effectively, particularly writing tasks, due to excessive anxiety and obsessionality. . . . When he came for treatment, he was struggling to make progress on his master's thesis. Although Mr. V socialized quite a bit, he reported that intimate relationships often felt "wooden." He was usually overcommitted, with an endless list of "shoulds" that he would constantly mentally review and remind himself how much he was failing to satisfy his obligations. A central theme throughout treatment was his tendency to be self-denigrating, loathing himself as a person deserving of punishment in some way yet being extremely provocative. . . . He also held very strong political beliefs, sure that his way of viewing things was superior to others.

(Bender, 2005, p. 413)

Distinguishing Between Obsessive-Compulsive Personality Disorder and Other Disorders

Obsessive-compulsive personality disorder is distinguished from OCD by the absence of true obsessions and compulsions. Rather, those with obsessive-compulsive personality disorder are preoccupied with details—as was Mr. V when writing his master's thesis—and are inflexible. Researchers are still trying to determine whether obsessive-compulsive personality disorder and OCD differ quantitatively or qualitatively. Research studies addressing this question have reported mixed findings (Albert et al., 2004; Eisen et al., 2006; Wu, Clark, & Watson, 2006). Most people with one of the two disorders do not have the other (Mancebo et al., 2005).

Understanding Fearful/Anxious Personality Disorders

Virtually nothing is known about the neurological bases of fearful/anxious personality disorders, but the apparent similarity between these disorders and anxiety disorders might indicate that the amygdala is involved. At present, however, this is merely inference and speculation. In contrast, psychological factors associated with these disorders have been identified. In particular, fear and anxiety underlie the three fearful/anxious disorders. Temperament—specifically being high in the dimension of harm avoidance—can contribute to the development of one of these disorders, especially avoidant personality disorder (Joyce et al., 2003; Taylor, Laposa, & Alden, 2004). In fact, many of the factors related to social phobia are also involved in avoidant personality disorder, which makes sense, given the overlap in the symptoms of the two disorders. For instance, people with social phobia are also high in the dimension of harm avoidance (Marteinsdottir et al., 2003). Moreover, people with both disorders have similar negative beliefs about themselves in relation to other people and avoid social situations for fear of embarrassing themselves (Meyer, 2002; Morey et al., 2003).

Cognitive and behavioral factors are thought to contribute to all three fearful/anxious personality disorders, as outlined in Table 13.27. For all three, patients avoid situations that lead to discomfort and anxiety: With avoidant personality disorder, patients avoid social situations; with dependent personality disorder, they avoid making decisions and having responsibility; and with obsessive-compulsive personality disorder, they avoid making mistakes and experiencing strong emotions. The avoidance perpetuates the cognitive distortions because the patients' fears go unchallenged (Beck, Freeman, & Davis, 2004; Farmer & Nelson-Gray, 2005).

Finally, social factors also contribute to these personality disorders. These factors include anxious or avoidant attachment style, which may have arisen in childhood as a result of particular interaction patterns with parents (Gude et al., 2004; Pincus & Wilson, 2001).

Treating Fearful/Anxious Personality Disorders

As for most other personality disorders, there is little research on the treatment of fearful/anxious personality disorders, and what research there is has focused primarily on avoidant personality disorder. The findings suggest that the treatment that is effective with social phobia—CBT that uses exposure to avoided stimuli as well as

Table 13.27 ▶ Maladaptive Views, Beliefs, and Strategies of Individuals with Fearful/Anxious Personality Disorders

Personality Disorder	View of Self	View of Others	Main Beliefs	Main Strategies
Avoidant	Socially inept, incompetent, vulnerable to rejection	Critical, demeaning, superior	"I may get hurt." "If people know the 'real' me, they will reject me." "It's terrible to be rejected, put down." "I can't tolerate unpleasant feelings."	Avoid evaluative situations and unpleasant thoughts or feelings
Dependent	Needy, weak, helpless, incompetent	Idealized as nurturant, supportive, competent	"I am helpless." "I need people to survive, to be happy."	Cultivate relationships in which dependence is accepted
Obsessive-Compulsive	Responsible, accountable, fastidious, competent	Irresponsible, casual, incompetent, self-indulgent	"I must not err." "I know what's best." "Details are crucial." "People <i>should</i> do better, try harder."	Perfectionism, control, criticism, punishment, thinks in terms of "shoulds"

Source: Beck, Freeman, & Davis, 2004, pp. 21, 36, 48–49.

cognitive restructuring of maladaptive beliefs and strategies—can also help people with avoidant personality disorder (Beck, Freeman, & Davis, 2004; Emmelkamp et al., 2006; Farmer & Nelson-Gray, 2005; Reich, 2000; Van Velzen, Emmelkamp, & Scholing, 1997). Treatment may also include family or couples therapy to help family members change their responses to—and thus the consequences of—the patient's maladaptive behaviors.

Table 13.28 summarizes the contrasting characteristics of the ten personality disorders.

Table 13.28 ► The Personality Disorders: A Summary

Personality Disorders	Affect	Behavior	Cognition	Social Functioning
Odd/Eccentric: Cluster A				
Paranoid	Easily feels betrayed and angry	Hypervigilant for betrayal	Distrustful/suspicious of others; reads malevolent meaning into neutral remarks	Generally avoids relationships
Schizoid	Emotionally constricted, detached	Avoids people when possible	Views relationships as messy and undesirable	Indifferent to praise or criticism; generally avoids relationships
Schizotypal	Generally emotionally constricted, but displays inappropriate affect and anxiety	Avoids people whenever possible	Perceptual distortions, ideas of reference, magical thinking	Generally avoids relationships
Dramatic/Erratic: Cluster B				
Antisocial	Aggressive feelings toward others, lack of empathy	Generally poor impulse control	Believes that he or she is entitled to break rules	Dominant in relationships
Borderline	Emotionally expressive, with inappropriately strong and rapid reactions	Poor impulse control	Dramatic shifts between overvaluing and undervaluing others; may develop paranoid thinking under stress	Alternately dominant and submissive in relationships
Histrionic	Rapidly shifting but shallow emotions	Relatively poor impulse control; strives to be center of attention	Some grandiosity, believes that he or she should be admired	Dominant in relationships
Narcissistic	No empathy; haughty towards others	Manipulates others	Grandiosity	Dominant in relationships
Fearful/Anxious: Cluster C				
Avoidant	Anxiety in social situations	Overcontrol of behavior	Excessively negative self-opinion; worries about being rejected or criticized	Submissive in relationships
Dependent	Anxiety about possible separations from others and having to function independently	Overcontrol of behavior	Believes that he or she is helpless and incompetent and so must rely on others	Submissive in relationships
Obsessive-Compulsive	Constricted in expression of emotion to others	Overcontrol of behavior	Perfectionism; rigid thinking; preoccupation with details, rules, and lists	Dominant and somewhat detached in relationships

Source: Pretzer & Beck, 2005; Skodol, 2005.

Key Concepts and Facts About Fearful/Anxious Personality Disorders

- The hallmark of avoidant personality disorder is social inhibition, which usually stems from feeling inadequate and being overly sensitive to negative evaluation. Although similar to social phobia, avoidant personality disorder has criteria that are more pervasive and involve a more general reluctance to take risks. CBT methods that are used to treat social phobia can also be effective with avoidant personality disorder.
- Dependent personality disorder is characterized by submissive and clingy behaviors, based on fear of separation; these behaviors are intended to elicit attention, reassurance, and decision making from other people. People with dependent personality disorder are chronically plagued by self-doubt and consistently underestimate their abilities; in fact, they may not know how to function independently.
- Obsessive-compulsive personality disorder is characterized by preoccupations with perfectionism, orderliness, and self-control and by low levels of flexibility and efficiency. These rigid personality traits may lead these people to have difficulty prioritizing and making decisions, and they are often intolerant of emotional or “illogical” behavior in others.
- Psychological and social factors that contribute to social phobia also contribute to avoidant personality disorders.

Making a Diagnosis

- Reread Case 13.9 about Marcus, and determine whether or not his symptoms meet the criteria for avoidant personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 13.10 about Matthew, and determine whether or not his symptoms meet the criteria for dependent personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 13.11 about Mr. V, and determine whether or not his symptoms meet the criteria for obsessive-compulsive personality disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Follow-up on Rachel Reiland

We can say with certainty that Rachel Reiland suffered from borderline personality disorder. In addition, she displayed significant elements of two other personality disorders: histrionic personality disorder (her dramatic behaviors may have been motivated by excessive emotional reactivity and a desire for attention) and obsessive-compulsive personality disorder (her rigid thoughts and behaviors may have been motivated by perfectionism). However, it is difficult to determine whether these aspects of her personality met the criteria for the diagnosis of a comorbid personality disorder. Her symptoms of borderline personality disorder were so pronounced that they might have masked additional personality disorders.

If a clinician interviewing Reiland had sought to assess the presence of possible comorbid personality disorders, he or she might have spoken with Reiland’s husband for his perspective, asked Reiland specific questions related to the other personality disorders under consideration, or asked her to complete a personality inventory or questionnaire (described in Chapter 3).

What happened to Reiland? In her memoir, she notes that she was hospitalized three times; the first time because of significant suicidal impulses. After discharge from that first hospitalization, she spent 4 years in intensive outpatient therapy with a psychiatrist—three times a week during the first 2 years of treatment. She was hospitalized twice more over the course of her therapy and again developed anorexia for a period of time. Her symptoms were sufficiently severe that her therapist imposed strict limits on their interactions; for instance, he banned physical contact of any kind. Although her therapist used psychodynamic therapy, he also incorporated elements of CBT and DBT into the treatment. For instance, the therapist addressed Reiland’s black-and-white thinking and validated her experiences while trying to help her accept her feelings without judging herself. In addition to the

SUMMING UP

Summary of Diagnosing Personality Disorders

A personality disorder is characterized by maladaptive personality traits that begin by young adulthood and continue through adulthood; these traits are relatively inflexible, are expressed across a wide range of situations, and lead to distress or impaired functioning. A personality disorder affects three areas of functioning: affect, behavior (including social behavior), and cognition. The diagnostic criteria for personality disorders were based on the assumptions that the maladaptive personality traits begin in childhood and are stable throughout life. These assumptions led to the disorders being placed on a separate axis (Axis II) of DSM-IV-TR. Subsequent research indicates that some Axis I disorders begin in childhood and that symptoms of personality disorders may improve over time.

Personality disorders may be assessed through diagnostic interviews, personality inventories, or questionnaires. The clinician may make the diagnosis based on the pattern of the patient's behavior and, given the preponderance of interpersonal problems that arise with personality disorders, may also rely on supplemental reports from family or friends.

In DSM-IV-TR, personality disorders are grouped into three clusters: Cluster A, characterized by odd or eccentric behaviors related to features of schizophrenia; Cluster B, characterized by dramatic and erratic behaviors and problems with emotional regulation; and Cluster C, characterized by anxious or fearful behaviors. The category of personality disorders in DSM-IV-TR has been criticized on numerous grounds.

The neuropsychosocial approach explains how personality disorders develop by highlighting the interactions among three sorts of factors: the effects of genes on temperament and the interaction of temperament, operant conditioning, dysfunctional beliefs, and insecure attachment that can result from childhood abuse or neglect. Treatments for personality disorders include medications for comorbid symptoms, CBT or psychodynamic therapy, and family education and therapy, as well as couples, interpersonal, and group therapy.

Thinking like a clinician

V.J. was 50 years old, never married, and had never been very successful professionally. He

hospitalizations and outpatient therapy, Reiland tried various medications, settling on antidepressants that she gradually stopped before her therapy ended.

Her treatment was successful. She wrote her memoir 8 years after her therapy ended; she developed and sustained the ability to regulate her moods, to control her impulses, and to have productive and enjoyable relationships.

was a salesman, and changed companies every few years, either because he was passed over for a promotion and quit, or because he didn't like the new rules—or the way that the rules were enforced—at the job. He'd been in love a few times, but it never worked out. He chalked it up to difficulty finding the right woman. He had some friends, but they were really people he'd known over the years and saw occasionally. Most of his positive social interactions happened in chat rooms or via e-mail, not face to face.

Is there anything about the information presented that would lead you to wonder whether he might have a personality disorder—if so, what was the information? (And if not, why not?) Based on what you have read, how should mental health clinicians go about determining whether V.J. might have a personality disorder or whether his personality traits are in the normal range? Do you agree with the way that DSM-IV-TR goes about classifying personality disorders—why or why not?

Summary of Odd/Eccentric Personality Disorders

The essential feature of paranoid personality disorder is a persistent and pervasive mistrust and suspiciousness, which is accompanied by a bias to interpret other people's motives as hostile. Although paranoid personality disorder and paranoid schizophrenia both involve suspicious beliefs, people with the personality disorder have some capacity to evaluate whether their suspicions are based on reality; they also tend to be suspicious about people they know. In contrast, the beliefs of people with paranoid schizophrenia are delusional, and they perceive threats as coming from strangers or objects.

Schizoid personality disorder is characterized by a restricted range of emotions in social interactions and few—if any—close relationships; people with this disorder have poor social skills. They report rarely experiencing strong emotions, and they prefer to be—and function best when—isolated from others.

Schizotypal personality disorder is marked by eccentric thoughts, perceptions, and behaviors, as well as by having very few close relationships. This personality disorder is characterized by three groups of symptoms:

cognitive-perceptual, interpersonal, and disorganized. Schizotypal personality disorder is viewed as a milder form of schizophrenia. Many of the factors that give rise to schizophrenia also appear to give rise to schizotypal personality disorder: genes and the prenatal environment; problems with attention, memory, and executive function as well as an impaired theory of mind; and physical abuse or neglect in childhood, insecure attachment, and discrimination.

Paranoid, schizoid, and schizotypal personality disorders are on the spectrum of schizophrenia-related disorders, and close relatives of people with any of these odd/eccentric personality disorders are more likely to have schizophrenia. Schizotypal personality disorder involves neurological abnormalities that are less severe than those associated with schizophrenia.

People with odd/eccentric personality disorders are reluctant participants in treatment. Treatment may address fundamental issues, such as isolation and suspiciousness. Treatment for schizotypal personality disorder may include antipsychotic medication (although at lower doses than used for psychotic disorders), CBT, social skills training, and family therapy.

Thinking like a clinician

Shawna has few friends; most of the time she's quiet and shy, avoiding eye contact. Occasionally, she mentions that her troubles—work, social, and financial—are because of the radiation coming out of the computer. She says it with a straight face, but it's hard to tell whether she's joking. When asked whether she's being serious, she reluctantly says that she's not, but it's not clear whether she's being honest. If you were asked to determine whether she has a personality disorder, what kinds of questions would you ask? Based on what you have read, what types of answers would distinguish somewhat quirky behavior from the truly odd behavior that characterizes a Cluster A personality disorder? If you determined that her behavior was odd enough to merit a diagnosis of a Cluster A (odd/eccentric) personality disorder, what would you look for in order to decide which of those disorders might be the best diagnosis? Could Shawna have more than one personality disorder? If not, why not? And if so, what might her other symptoms be?

Summary of Dramatic/Erratic Personality Disorders

The hallmark of antisocial personality disorder is a persistent disregard for the rights of others, which may lead these people to violate rules or laws or to act aggressively. To be diagnosed with this personality disorder, an individual must have exhibited symptoms of conduct disorder before the age of 15. The diagnostic criteria for antisocial personality disorder overlap with aspects of psychopathy. However, psychopathy is defined by a more restrictive set of criteria, which focus on emotional and interpersonal characteristics, such as a lack of empathy, as well as antisocial behaviors. In contrast, for antisocial personality disorder, the focus is on behaviors, particularly criminal behaviors. More criminals are diagnosed with antisocial personality disorder than with psychopathy.

Psychopathy and antisocial personality disorder are thought to arise from feedback loops among various factors, including genes and temperament, lack of empathy, classical and operant conditioning, abuse or neglect or inconsistent discipline in childhood, parents' criminal behavior, and attachment style. Treatment for psychopathy has generally not been successful; treatment for antisocial personality disorder focuses on modifying specific behaviors and has some degree of success, at least temporarily, in motivated individuals.

Borderline personality disorder is characterized by volatile emotions, an unstable self-image, and impulsive behavior in relationships. People with this disorder have problems with emotional regulation—which is probably related to their temperament—and may engage in self-harming behaviors or try to commit suicide. Factors that contribute to borderline personality disorder include the genetic and neurological underpinnings of emotional dysregulation, a relatively low threshold for emotional responsiveness, an easily changeable sense of self, cognitive distortions, and a history of abuse, neglect, or feeling invalidated by others. Treatment for borderline personality may include medication, CBT, DBT, intensive psychodynamic therapy, and IPT.

The hallmark of histrionic personality disorder is attention seeking, usually through exaggerated emotional displays. Symptoms may also include a sense of boredom or emptiness and a low tolerance for frustration.

Narcissistic personality disorder is characterized by a grandiose sense of self-importance and a constant desire for praise and admiration. People with this disorder may also feel a sense of entitlement, behave arrogantly, and have difficulty understanding other people's points of view.

Thinking like a clinician

In high school and college, Will acted in school plays. Now in his 30s, he travels a lot, making presentations for his job, and so has a lot of independence. He likes the freedom of not having a boss looking over his shoulder all the time, and he enjoys making presentations. Because no one really knows how many hours he works, he sometimes starts late in the morning or quits early; then, he heads for a bar to down a few beers. Occasionally, he takes whole days off—after he's had too much to drink the night before. He's been through a series of girlfriends, never staying with one for more than 6 months. Lately, though, his single status has been bothering him, and he's been wondering why there don't seem to be any decent women out there.

In what ways does Will seem typical of someone with a Cluster B (dramatic/erratic) personality disorder? In what ways is he unusual? What would you need to know before you could decide whether he had a dramatic/erratic personality disorder? Which specific personality disorder seems most likely from the description of him, and why? Why is—or isn't—this information enough to make a diagnosis?

Summary of Fearful/Anxious Personality Disorders

The hallmark of avoidant personality disorder is social inhibition, which usually stems from feeling inadequate or being overly sensitive to negative evaluation. Although similar to social phobia, avoidant personality disorder has criteria that are more pervasive and involves a more general reluctance to take risks. CBT methods that are used to treat social phobia can also be effective with avoidant personality disorder.

Dependent personality disorder is characterized by submissive and clingy behaviors, based on fear of separation; these behaviors are intended to elicit attention, reassurance, and decision making from other people. People with dependent personality disorder are chronically plagued by self-doubt and consistently underestimate their abilities; in fact, they may not know how to function independently.

Obsessive-compulsive personality disorder is characterized by preoccupations with perfectionism, orderliness, and self-control and by low levels of flexibility and efficiency. These rigid personality traits may lead these people to have difficulty prioritizing and making decisions, and they are often intolerant of emotional or "illogical" behavior in others.

Thinking like a clinician

Juan and his wife, Beatriz, are from Argentina. They have been referred to mental health services by their family doctor. Beatriz always brings her husband with her to her doctor's appointments, and she wants her husband in the room during the examination, although her English is more than sufficient to express herself and understand the doctor.

Beatriz and Juan happened to mention at her last medical visit that she never leaves the house if Juan isn't with her. She didn't see why she should, because Juan is happy to go with her wherever she needs to go. She said that she likes it this way—that she doesn't feel "stuck" at home and that Juan pretty much takes care of whatever she doesn't feel able to do.

Before thinking about a possible diagnosis, what specific areas of Beatriz's functioning would you want to know more about, and why? What other types of information would you want to have (for example, about cultural issues), and why? Might Beatriz be suffering from an Axis I disorder? If so, which one, and what would you need to know to be relatively certain of that? If not, why not? What personality disorder or disorders might she have (or does she have none)? On what information do you base your judgment?

Childhood Disorders

Lela and Carlos Enriquez have three children: Javier, Pia, and Richie. It's been a very challenging year for the family, full of heartache. All three children have been having various difficulties at home or at school. Lela and Carlos are trying to figure out what, exactly, the problems are and what can be done about them.

The most troubling problem concerns their youngest son, Richie. He's almost 2 years old, but he has yet to smile at his parents—or anyone. He's not talking either, and although he seems to understand what people say to him, he is a bit slow to respond. Whereas most toddlers are talking in (at least) 2- or 3-word sentences, Richie doesn't even say single words. His doctor wasn't that worried when she saw him at his last physical exam a few months ago: "Well, kids sometimes take a while to talk. Let's give him a few more months and if he hasn't started talking by then, give me a call." Richie also seems shy in the extreme—he doesn't even look people in the eye.

Richie's older siblings have also been having problems. Javier is 10 years old, and he's had both academic and social problems at school; his teacher suggested he receive a thorough evaluation. His 8-year-old sister, Pia, has been a bit of a puzzle. On her last report card, her teacher noted that she's very bright but doesn't seem to be working as hard as she could.

Like Richie, Pia, and Javier, many children have problems socially or academically or achieve developmental milestones, such as walking and talking, later than the average child. When are such difficulties part of the range of normal development, and when do they signal a larger problem? This chapter addresses this question by exploring various disorders listed in DSM-IV-TR that typically are first diagnosed during infancy, childhood, or adolescence. For these disorders, the timing of the diagnosis contrasts with that of most of the disorders discussed in previous chapters (e.g., anxiety, depression, substance-related disorders), which typically are first diagnosed during adulthood. Nonetheless, children can be diagnosed with many of the Axis I disorders discussed in previous chapters.

We begin this chapter by examining mental retardation—a disorder that can profoundly affect the lives of children and their families and that may require special schools or residential placements as well as other special services. We then examine a set of disorders referred to as *pervasive developmental disorders*, which are often comorbid with mental retardation and may require special school placements and special services. We next turn to disorders that may

not affect children and their families as much, although they still cause significant distress and/or impair functioning; learning disorders and disorders of disruptive behavior and attention. In the final section, we examine briefly other disorders of childhood, which have symptoms that can overlap with those of other psychological disorders or problems.

Some of the disorders discussed in this chapter are lifetime diagnoses. Individuals and their family members can become adept at managing, compensating for, and working around the symptoms of these disorders. Neurological factors are often the most direct cause of many of the disorders discussed in this chapter, such as mental retardation and learning disorders; psychological and social factors may play a role, but often only an indirect one. For instance, poor pregnant mothers and children raised in poverty (social factor) may be more likely to be exposed to substances that cause certain types of mental retardation in children. Psychological and social factors also play a role in how well an individual adapts to and compensates for his or her disorder.

For many of the disorders in this chapter, the specific mechanisms of feedback loops among the three factors are not as well documented as they are for disorders discussed in most other chapters. For this reason, some of the sections that describe the contributions of neurological, psychological, and social factors do not include information on feedback loops among these factors.

Mental Retardation

When either Lela or Carlos calls Richie's name, he often seems to ignore it. They can tell that he's not deaf—he clearly notices street noises and other sounds and he startles in response to loud noises. He seems to understand *some* of what people say to him, but his cognitive abilities are less developed than Javier's and Pia's were when they were his age; Richie's intellectual functioning definitely doesn't seem normal. Could he be mentally retarded?

In this section we examine mental retardation in more detail—its criteria and causes and the treatments provided to people with this disorder.

What Is Mental Retardation?

Mental retardation refers to intelligence that is significantly below normal—an IQ approximately equal to or less than 70 (where the mean IQ is set at 100)—and that impairs daily functioning. The deficits in intellectual ability and daily functioning (see Table 14.1) must have begun before 18 years of age, and thus cannot be the result of brain trauma in adulthood. The IQ cutoff of 70 or less is two standard deviations or more below average ability. Mental retardation, along with personality disorders, is an Axis II diagnosis because the authors of DSM-IV wanted to ensure that symptoms of Axis I disorders do not overshadow the possibility that a given individual has comorbid mental retardation (or a personality disorder) (American Psychiatric Association, 2000). The term *intellectual disability* is sometimes used as a synonym for mental retardation.

DSM-IV-TR specifies the following four levels of mental retardation, which are set by ranges of IQ scores (Criterion A). In general, the lower the IQ score, the more impaired the individual is likely to be. However, an individual's IQ scores can vary by about 5 points because of testing error, so the ranges generally allow a 5-point leeway for assigning the level of retardation and level of adaptive functioning:

- **Mild mental retardation.** The IQ score can range from 50–55 to 70; 85% of people with mental retardation fall into this group. People in this mild

Table 14.1 ▶ DSM-IV-TR Diagnostic Criteria for Mental Retardation

A. Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered IQ test (for infants, a clinical judgment of significantly subaverage intellectual functioning).

B. Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age by his or her cultural group) in at least two of the following areas:

communication,
self-care,
home living,
social/interpersonal skills,
use of community resources,
self-direction,
functional academic skills,
work,
leisure,
health, and
safety.

C. The onset is before age 18 years.

range may be able to function relatively independently with training but usually need additional help and support during stressful periods.

- **Moderate mental retardation.** The IQ score can range from 35–40 to 50–55; 10% of people with mental retardation fall into this group. Although they are not able to function independently, with training and supervision, people in this group may be able to perform unskilled work and take basic care of themselves.
- **Severe mental retardation.** The IQ score can range from 20–25 to 35–40; approximately 3–4% of people with mental retardation fall into this group. Adults in this group are likely to live with their family or in a supervised setting and are able to perform simple tasks only with close supervision. They may be able to learn to read a few basic words and do simple counting. During childhood, they may begin speaking later than other children.
- **Profound mental retardation.** The IQ score falls below 20 or 25; 1–2% of those with mental retardation fall into this group. People in this group need constant supervision or help to perform simple tasks; they are likely to have significant neurological problems.

Figure 14.1 illustrates the IQ scores associated with the four levels of mental retardation.

Although an individual's IQ score serves as a guide, the most important criterion for determining the level of mental retardation is the level of adaptive functioning (Criterion B), which indicates how well the person can cope with life's daily demands compared to others of the same age and cultural background. Information from parents and teachers may help the clinician to determine the individual's ability to function. Depending on IQ and level of adaptive functioning, someone with mental retardation may require anywhere from minimal supervision to constant care. Many, like Larry in Case 14.1, have needs and abilities that fall somewhere in the middle.

CASE 14.1 ► FROM THE OUTSIDE: Mental Retardation

Larry, a 34-year-old man with moderate mental retardation . . . had been referred for complaints of seeing “monsters,” “scary faces,” and “the bogeyman.” He initially appeared paranoid and delusional, describing the feared bogeyman in detail. An assessment of possible neurochemical or physical factors that might help explain the recent onset of these symptoms yielded no significant diagnostic information. . . .

Larry's perception of monsters was specific to certain situations, such as being alone in a dark room. . . .

Specifically, when asked to go alone to any dark place [including the dark stairwell in his group home, where Larry must go to carry out his assigned chore of taking down the trash], he became agitated, resisted, and made loud statements about monsters and scary faces. . . .

Larry's monsters could be attributed to his limited means of communicating his fear of being alone in the dark. [It appears, then, that Larry has a phobic response to the dark.] . . .

Even if the residence staff excused him from this task, Larry would remain agitated because he believed he was shirking an important responsibility.

(Nezu, Nezu, & Gill-Weiss, 1992, pp. 78, 164)

Larry had two disorders: mental retardation and a specific phobia. Because of his mental retardation, he had difficulty explaining his fears. He received CBT treatment for his phobia, which was successful, and he became able to go down to the basement without fear.

Like people of normal intelligence, people with mental retardation exhibit a wide variety of personality characteristics: Some are passive or easygoing, and others are impulsive or aggressive; those who have severe or profound mental retardation—or even moderate mental retardation, like Larry—may have difficulty communicating

New Line Cinema/Courtesy Everett Collection

Like Sean Penn's character in the movie *I Am Sam*, people with mild mental retardation can, with training, learn to function independently. In this scene Penn is shown with Michelle Pfeiffer, who plays his lawyer in his fight to retain custody of his young daughter.

Figure 14.1

Note: The high-end cutoff for profound, severe, and moderate mental retardation can be 5 IQ points higher than noted in this graph if the individual has a low level of functioning for that IQ score.

14.1 ► The Four Levels of Mental Retardation

There are four levels of mental retardation, each of which corresponds to a range of IQ scores. As the graph indicates, most people with mental retardation fall in the *mild* range, with increasingly smaller numbers of people having more severe retardation.

Table 14.2 ▶ Mental Retardation Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Approximately 1% of the general population has mental retardation; however, prevalence estimates vary depending on the survey method used and the particular population studied.
Onset
<ul style="list-style-type: none"> Severe and profound retardation are generally identified at birth, although in some cases, mental retardation is caused by a medical condition later in childhood, such as head trauma. Mild retardation is sometimes not diagnosed until relatively late in childhood, although the onset may have been earlier.
Comorbidity
<ul style="list-style-type: none"> Compared to the general population, people with mental retardation are three to four times more likely to have an additional psychological disorder. Among the most common comorbid disorders are major depressive disorder and attention-deficit/hyperactivity disorder. Symptoms of mental retardation may affect the presentation of symptoms of a comorbid disorder; people with severe or profound mental retardation, for instance, may not be able to report feelings of hopelessness or depressed mood.
Course
<ul style="list-style-type: none"> The diagnosis is typically lifelong for moderate to profound mental retardation, but beneficial environmental factors can improve adaptive functioning for those with mild mental retardation to the point where they no longer meet all the criteria for the disorder. Educational opportunities, support, and stimulation can improve the level of functioning.
Gender Differences
<ul style="list-style-type: none"> Mental retardation occurs more frequently in males, with a male-to-female ratio of 1.5 to 1.
Cultural Differences
<ul style="list-style-type: none"> Although the criteria for mental retardation used in other countries are similar to those used in the United States, they are not always the same; such differences may account for the higher prevalence rates in some other countries, such as 4.5% in France (Oakland et al., 2003).
Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

verbally, which can heighten aggressive or impulsive tendencies. Unfortunately, people with mental retardation are more likely than average to be exploited or abused by others. Table 14.2 lists additional facts about mental retardation.

Understanding Mental Retardation

There are many neurological paths to mental retardation, some of which arise because the fetus is exposed to certain types of substances (such as drugs or a virus) or to other stimuli (such as radiation); such harmful substances and stimuli are referred to as **teratogens**. Mental retardation may also arise from particular complications during labor (such as occurs when a newborn receives insufficient oxygen during birth) or from exposure to high levels of lead prenatally or during childhood (which can occur when young children eat lead-based paint chips or inhale lead-based dust from sanded paint; prior to 1978, lead was an ingredient used in paints).

Neurological Factors: Teratogens and Genes

One type of teratogen is environmental toxins, to which a fetus typically is exposed through the placenta after the toxin has entered the mother's bloodstream. Examples of environmental toxins include synthetic chemicals such as methyl mercury,

Teratogens

Substances or other stimuli that are harmful to a fetus.

Table 14.3 ▶ Genetic Causes of Mental Retardation

Cause of Mental Retardation	Genetic Abnormality
• <i>Down syndrome</i>	• Abnormality in chromosome 21
• <i>Rett's disorder</i> (females only)	• Abnormality in X chromosome (which is lethal for male fetuses)
• <i>Fragile X</i> (the most common cause of inherited mental retardation)	• Repetition of a piece of genetic code on the X chromosome that becomes progressively more severe in each generation
• <i>Prader-Willi and Angelman Syndromes</i>	• Deletion on chromosome 15 that has different consequences depending on which parent's genes contribute the deletion
• <i>Phenylketonuria</i> (PKU)	• A genetically based defect in an enzyme, <i>phenylalanine hydroxylase</i> , that leads to a failure to convert phenylalanine to tyrosine. Unconverted phenylalanine is toxic to brain cells, leading to mental retardation. Mental retardation can be prevented if PKU is identified (through a blood test at birth) and the individual adheres to a diet that restricts phenylalanine.
• <i>Congenital hypothyroidism</i>	• Inadequate production of thyroid hormone caused by a genetic mutation. The fetus gets thyroid hormone from the mother, but after birth the deficiency leads to defects in the developing brain. If hypothyroidism is not detected within the first 3 months of life, the damage is not reversible even with thyroid hormone replacement.

polychlorinated biphenyls (PCBs), and mixtures of chemicals such as those found in pesticides. Exposure to these toxins in the first trimester of pregnancy can affect important early developmental processes of the central nervous system (Lanphear, Vorhees, & Bellinger, 2005). Mental retardation may also arise because of a variety of genetic abnormalities, listed in Table 14.3.

The cognitive and behavioral deficits observed in people with mental retardation arise because the brain does not process information appropriately, often because of abnormal brain structure. In fact, using evidence from autopsies and neuroimaging, researchers report that people with some forms of mental retardation have larger heads, which may suggest larger brains (Herbert, 2005), which in turn could result from any number of factors, including larger fluid-filled ventricles in the center of the brain, bulkier white matter (myelin around the axons), or greater numbers of glial cells.

In contrast, with other forms of mental retardation, people have smaller than normal heads. For example, this occurs in people who suffer from *fetal alcohol syndrome*. This syndrome is a set of birth defects caused by the mother's alcohol use during pregnancy (alcohol is a teratogen). Moreover, smaller head size may arise because the sizes of some specific brain areas are reduced. In fetal alcohol syndrome, the cerebellum, the basal ganglia, and the corpus callosum are affected (Riley & McGee, 2005), all of which are involved in coordination and smooth motor movement. The frontal lobes are also affected, specifically the portions involved in planning, carrying out tasks, and controlling impulsive behavior. All of these activities are difficult for many children with fetal alcohol syndrome.

Although severe or profound mental retardation often involves global abnormalities, each case of mild or moderate mental retardation may present a unique profile of specific impaired abilities, related to the particular cause of the retardation.

Psychological Factors: Problem Behaviors

Individuals with mental retardation often show two types of problematic behaviors that are not specifically mentioned in the DSM-IV-TR criteria: (1) **stereotyped behaviors** (also referred to as *stereotypies*), which are repetitive behaviors that don't serve a function, such as hand flapping, slight but fast finger and hand motions,

David Young-Wolff/Photo Edit

The characteristic facial features associated with fetal alcohol syndrome include small eyes, a proportionately large smooth space between the upper lip and the nose, and a thin upper lip.

Stereotyped behaviors

Repetitive behaviors—such as body rocking—that do not serve a function; also referred to as *stereotypies*.

When this child gets excited, she engages in the stereotyped behavior of hand-flapping. Other stereotyped behaviors exhibited by people with mental retardation include rocking back and forth and repeatedly moving a finger.

Maria Platt-Evans/Photo Researchers

and body rocking (American Psychiatric Association, 2000); and (2) *self-injurious behaviors*, such as hitting the head against something and hitting or biting oneself. People with mental retardation who exhibit both stereotypic behaviors and self-injurious behaviors have greater deficits in nonverbal social skills than those with only one type of problematic behavior (Matson et al., 2006). Other problematic behaviors that often go along with mental retardation include consistently choosing to interact with objects rather than people, inappropriately touching others, and resisting physical contact or affection. How or why all these behaviors arise is not yet known.

Social Factors: Understimulation

Another way in which mental retardation can arise is when an infant's environment is severely understimulating or the infant is undernourished (Dennis, 1973; Dong & Greenough, 2004; Skeels & Dye, 1939). However, in 30–40% of cases, there is no clear cause for the mental retardation; when there are clear etiological factors, the diagnosis is generally in the severe or profound range.

In sum, most cases of mental retardation arise primarily from neurological factors—genes or teratogens, which in turn lead to abnormal brain structure and function, leading to cognitive deficits. Moreover, children with mental retardation may exhibit stereotyped or self-injurious behaviors.

Treating Mental Retardation

Mental retardation cannot be “cured,” but interventions can help people to function more independently in daily life. Such interventions are designed to improve the person's ability to communicate and other skills. But more than that, clinicians try to prevent mental retardation from arising in the first place. Prevention efforts seek to avert or reduce the factors that cause mental retardation.

Targeting Neurological Factors: Prevention

Because the key causes of mental retardation are neurological, this type of factor is the target of prevention efforts. Two successful prevention efforts focus on *phenylketonuria* (PKU) and exposure to lead. Since the 1950s, virtually all newborns in the United States receive a test to detect whether they have PKU, which consists of a problem metabolizing the enzyme phenylalanine hydroxylase. For newborns testing positive, lifelong dietary modifications can prevent any brain damage, thus preventing mental retardation. Another successful prevention effort involves childhood exposure to lead, which can lead to brain abnormalities. As noted earlier, lead was banned as an ingredient in paint in 1978; laws were passed that required landlords and homeowners to inform any prospective renters or buyers of any known lead paint on the property. Beginning in the 1970s, lead was also phased out as an additive to gasoline. As a result of these measures, lead exposure—and lead-induced mental retardation—has decreased.

There are no neurological treatments for mental retardation, although symptoms of comorbid disorders may respond to medication.

Targeting Psychological and Social Factors: Communication

Given the deficits and heterogeneous symptoms that accompany mental retardation, no single symptom is the focus of all psychological and social treatments. Rather, psychological and social treatments depend on the individual's specific constellation

of symptoms of mental retardation and possible comorbid disorders. In some cases, treatment is designed to target significant communication deficits. Such treatment may teach nonvocal communication, for example, using a technique called the Picture Exchange Communication System (PECS) (Bondy & Frost, 1994). With this system, children learn to give a picture of the desired item to someone in exchange for that item. Important elements of the program include learning to recognize which picture corresponds to what is wanted (cognitive skill), going over to someone to give the picture (social skill), and responding appropriately to the question “What do you want?” (social and communication skills).

Targeting Social Factors: Accommodation in the Classroom—It’s the Law

With the passage of the Americans with Disabilities Act in 1990 and the subsequent Individuals with Disabilities Education Act (IDEA) in 1997, eligible children with disabilities between the ages of 3 and 21 are guaranteed special education and related services that are individually tailored to the child’s needs, at no cost to the parents. Each child with disabilities receives a comprehensive evaluation, and the child is placed in the least restrictive environment that responds to his or her needs. An *individualized education program* (IEP) specifies educational goals as well as supplementary services or products that should be used to help the student utilize the regular curriculum.

For many children, one goal of the IEP is to facilitate **inclusion**—placing students with disabilities in a regular classroom, with guidelines for any accommodations that the regular classroom teacher or special education teacher should make. Note that *mainstreaming* is not the same as inclusion; mainstreaming simply refers to placing a child with disabilities into a regular classroom, with no curriculum adjustments to accommodate the disability. With inclusion, a child with mild mental retardation placed in a regular classroom may take much longer than his or her classmates to learn to read, and his or her reading fluency will not be as high as that of classmates. At school, such children may meet regularly with a speech and language therapist and a reading and math specialist during periods when the rest of the class is doing work that is beyond their ability.

Legal mandates have also brought people with mental retardation (and other disabilities) out from the shadows of institutional living into society: Depending on the severity of their retardation, they live in communities, hold jobs, and have families.

With the Picture Exchange Communication System, a child who has mental retardation with poor verbal communication skills can make his or her desires known: The child presents a card with the picture of the desired object to another person, who then may give the actual object to the child.

Like this girl with Down syndrome, youngsters with mild to moderate mental retardation may be placed in regular classrooms, either as part of inclusion (in which the teacher makes specific accommodations based on the child’s special needs) or mainstreaming (in which the teacher doesn’t make specific accommodations).

Inclusion

The placement of students with disabilities in a regular classroom, with guidelines for any accommodations that the regular classroom teacher or special education teacher should make.

In some cases, children with mental retardation (or other disabilities) may frequently behave in ways that disrupt the class—yelling, having temper tantrums, and acting aggressively toward others. In such cases, the children may be transferred to schools for students with special needs who cannot be accommodated in a regular classroom.

Is mental retardation an appropriate diagnosis for Richie Enriquez? It may well be—his language abilities are significantly delayed. However, he also has additional symptoms that are not explained by mental retardation—he avoids eye contact and hardly smiles. In the next section, we'll examine a set of disorders that might better account for these problems.

Key Concepts and Facts About Mental Retardation

- The diagnosis of mental retardation requires both an IQ score at or below 70 *and* impaired daily functioning. The four levels of mental retardation are mild, moderate, severe, and profound. Some people with mental retardation—particularly at the severe or profound level—may have difficulty communicating verbally.
- Neurological factors are the primary direct cause of most cases of mental retardation—usually a genetic abnormality or prenatal exposure to a teratogen such as alcohol. In turn, the genetic abnormality or teratogen alters brain structure and function.
- Although mental retardation cannot be cured, many types can be prevented, including PKU-related retardation (through early detection and dietary modification) and retardation caused by lead poisoning (by removing lead from the environment). Interventions are designed to improve the person's functioning by increasing his or her communication and daily living skills.
- Children whose symptoms make verbal communication difficult may be taught alternative methods of communication, such as the Picture Exchange Communication System (PECS).
- Legally, children with mental retardation are entitled to special education and related services, tailored to their individual needs through an individualized education program (IEP).

Making a Diagnosis

- Reread Case 14.1 about Larry, and determine whether or not his symptoms meet the criteria for mental retardation. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision? If you think he did have mental retardation, what level of retardation do you think he has and why—on what do you base your decision?

Pervasive Developmental Disorders

Richie Enriquez exhibits some behaviors that are not typical of individuals diagnosed with mental retardation: He avoids making eye contact with people and can spend hours—literally hours—playing with a glittery plastic ball. When his mother, Lela, takes the toy away from him, perhaps because it's time for lunch, he has a nuclear-sized temper tantrum: "He screams, he cries, he hits his head against the wall. . . . I don't know what to do. When I try to hold him, to comfort him, it seems to make things even worse. I've never seen a child like him." Carlos notes that "if the evening routine—dinner, bath, three books, bed—varies, if I forget to read the third book, Richie freaks out, rocking himself and screaming. And he has no interest in playing with Javier and Pia—even though they try so hard to get him to play or to laugh." From these descriptions, Richie's behaviors sound like symptoms of autism, a pervasive developmental disorder.

Pervasive developmental disorders are a set of disorders that have in common severe deficits in communication and in social interaction skills, and may also involve stereotyped behaviors and narrow interests. The word *pervasive* indicates that the symptoms affect all areas of the individual's life. Pervasive developmental disorders primarily arise from neurological abnormalities and dysfunctions (Kundert & Trimarchi, 2006; Ozonoff, Rogers, & Hendren, 2003). Most pervasive developmental disorders become evident during infancy or early childhood, and many children also have comorbid mental retardation, which may be true of Richie. Children for whom mental retardation is the only psychological

Pervasive developmental disorders

A set of developmental disorders that have in common severe deficits in communication and in social interaction skills and may also involve stereotyped behaviors and narrow interests.

disorder usually look people in the eye, and they tend to respond when hearing their names and to smile at other people. In contrast, children with a pervasive developmental disorder—with or without mental retardation—generally avoid eye contact and shy away from social interactions.

Four specific disorders are included in the DSM-IV-TR category of pervasive developmental disorders: *autistic disorder*, *Asperger's disorder*, *childhood disintegrative disorder*, and *Rett's disorder*. Children who have symptoms of a pervasive developmental disorder that impairs their functioning but do not meet the criteria for any of these four disorders will be diagnosed with *pervasive developmental disorder not otherwise specified*.

We first examine *autism spectrum disorders*—what they are, their causes and treatments—and then briefly consider the two less common pervasive developmental disorders that include profound neurological abnormalities: *childhood disintegrative disorder* and *Rett's disorder*.

Autism Spectrum Disorders

The term *autism spectrum disorders* is sometimes used as a synonym for *pervasive developmental disorders*; however, many researchers and clinicians consider autistic spectrum disorders to include only the two disorders that have related symptoms and etiology: autistic disorder and Asperger's disorder (Towbin, Mauk, & Batshaw, 2002). This is how we will use the term in this chapter. By “spectrum” we imply that there is a continuum, from mild to severe, and a given individual can fall somewhere along that continuum.

Autism: What Is Autistic Disorder?

Autism, or as is it named in DSM-IV-TR, **autistic disorder**, is characterized by delayed or impaired communication and social skills, along with restricted and repetitive behaviors and interests. The dysfunction is pervasive: It is severe and spans a number of areas of childhood development. Table 14.4 lists the DSM-IV-TR criteria. Among the pervasive developmental disorders, autistic disorder has the most specific diagnostic criteria.

People with autism tend to be oblivious to—and so appear to ignore—others. Younger children with autism appear to be uninterested in making friends. Some older children may want to make friends, but they don't understand the basic rules of social interaction; thus, their attempts are unlikely to be successful. To understand how symptoms of autism translate into daily life, consider the following list of “peculiarities” that a mother compiled about her 4-year-old son, George, before he was diagnosed with autism (quoted verbatim from Moore, 2006, pp. 94–95):

- He talks [by reciting] quotations and by imitating adult speech.
- Has poor social interaction. Doesn't know how to play with others.
- Avoids eye contact with strangers.
- He is very excitable (easily aroused, not easy to calm).

Autistic disorder

A pervasive developmental disorder that arises in childhood and is characterized by delayed or impaired communication and social skills, along with restricted and repetitive behaviors and interests; also referred to as *autism*.

Table 14.4 ▶ DSM-IV-TR Diagnostic Criteria for Autistic Disorder

<p>A. A total of six (or more) items from (1), (2), and (3), with at least two from (1), and one each from (2) and (3):</p>
<p>(1) qualitative impairment in social interaction, as manifested by at least two of the following:</p> <ul style="list-style-type: none"> (a) marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction; (b) failure to develop peer relationships appropriate to developmental level; (c) a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest); (d) lack of social or emotional reciprocity. <p>(2) qualitative impairments in communication as manifested by at least one of the following:</p> <ul style="list-style-type: none"> (a) delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime); (b) in individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others; (c) stereotyped and repetitive use of language or idiosyncratic language; (d) lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level. <p>(3) restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:</p> <ul style="list-style-type: none"> (a) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus; (b) apparently inflexible adherence to specific, nonfunctional routines or rituals; (c) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements); (d) persistent preoccupation with parts of objects.
<p>B. Delays or abnormal functioning in at least one of the following areas, with onset prior to age 3 years:</p>
<p>(1) social interaction;</p> <p>(2) language as used in social communication;</p> <p>(3) symbolic or imaginative play.</p>
<p>C. The disturbance is not better accounted for by Rett's Disorder or Childhood Disintegrative Disorder [both discussed later in this chapter].</p>

- He complains about strong stimuli, such as the sun, loud noises.
- Abnormalities of attention, including the ability to shut people out and be absorbed in something trivial for a long time.
- Loves nature, will stand and look at the moon for as long as he is allowed, despite freezing weather.
- Has a strong aversion to strangers, groups, and crowds.
- Obsessive.
- Ritualistic.
- Lines up [Lego bricks or matches them by color, but] doesn't build. Always destroys.
- Occasionally plays with feces.
- Doesn't dress or undress—just beginning to put on trousers and coat.
- Could recognize simple words at twenty months.
- Has a strong reaction to colors.
- Never asks questions except where is Mummy, Daddy, Sam.
- Only just starting to correlate facial expressions of others to emotion.

These behaviors might not be that unusual for a toddler, but they are definitely not typical for a 4-year-old. The items on George's mother's list span the problem areas that are the hallmarks of autism: impaired social interactions, impaired communication, and restricted and repetitive behaviors. Some of George's symptoms—symptoms of autism—overlap with symptoms of childhood schizophrenia; playing with feces, not dressing oneself, and becoming very upset in response to unwanted change could be signs of disorganized symptoms of schizophrenia. However, symptoms of autism are present before age 3, and symptoms of childhood schizophrenia arise *after* age 3.

When assessed with an intelligence tests that includes both verbal and visual elements, many individuals with autism are also diagnosed as having mental retardation. When researchers use an intelligence test that does not rely on verbal instructions or responses, however, intelligence scores of individuals with autism are often significantly higher—in or above the average intelligence range (Dawson et al., 2005). Moreover, unlike those with mental retardation, people with autism may not be impaired in all domains (though, as a rule, the impairments are general enough to be considered “pervasive”). In fact, about 20% of people with autism have pockets of unique skills relating to art, music, numbers, or calendars, such as the ability to identify the day of the week on which a given date fell, even when the date is many years in the past (Hermelin, 2001); such people are sometimes referred to as *autistic savants*. James, the person described in Case 14.2, has a remarkable ability to remember information he has heard.

CASE 14.2 ► FROM THE OUTSIDE: Autistic Disorder

James was the third of four children, born following an uncomplicated pregnancy and labor. His health during the first 3 months of life was good, but shortly thereafter his mother expressed concern because of his sensitivities to light and sound, his failure to make an anticipatory response to being picked up, his fluctuating moods between inconsolable crying and extreme passiveness, and his failure to look at her when she fed him. She reported that he preferred lying in his crib, staring at the mobile, to being held or played with. Because his motor milestones appeared at the appropriate times, James's pediatrician reassured his mother that his development was fine. By age 16 months, James had not begun to babble or say single words, and spent most of his time in a corner, repetitively moving toy cars back and forth. At 20 months, other symptoms emerged: he developed unusual hand movements and body postures; his obliviousness to people increased; he reacted to even the most subtle interruption in his routine or other changes in the world with extreme disorganization and panic; he developed a fascination with light switches and with studying tiny bits of paper and twigs.

At 4 years, James had not yet begun to speak socially to others, but could identify by name many numbers and all of the letters of the alphabet. . . . He persisted in lining up objects in the most complex patterns, but could never use objects appropriately. . . . At about the age of

4½ years, he began to echo long and complicated sentences, some of which his mother reported he may have heard days or even weeks before. He was able to complete puzzles designed for 8- and 9-year olds quickly, but was unable to reproduce a line or circle.

At about age 5, James made his first spontaneous statement. His mother reported that he had been looking at the sky and said, “It looks like a flower.” He did not speak again for 8 months, but then began talking in full sentences. . . . When he met strangers, he mechanically introduced himself without ever establishing eye contact, and then rushed on to ask what the person’s birthday, anniversary, and social security number were, often appearing to pause long enough to get the answers. Years later, upon re-meeting the person, he was able to recite back these facts.

(Caparulo & Cohen, 1977, pp. 623–624; case printed in Sattler, 1982, p. 474)

Like children with mental retardation (but unlike other children), children who have autism (1) tend to engage in very repetitive play and (2) often display stereotyped behaviors. They insist on repeating the same behaviors or activities for much longer periods than other children do. People with autism also become distressed when certain routines are not carried out or completed, as was Richie when his father varied the evening activities in any way; to calm themselves down, they may rock themselves, as did Richie.

For the most part, people with autism do not go through childhood milestones (language, social, or motor) in a normal fashion. They may speak with a monotone voice, and the rhythm of their speech may be odd. Moreover, they often have a variety of problems with attention and may be impulsive or aggressive; they may be more sensitive to sensory stimuli, leading them to shun physical contact with others. Typically, children with autism have only one narrow interest, such as the names of subway stations. Richie probably has mental retardation *and* autism: Mental retardation best explains his general cognitive slowing and his language problems, which are not limited to social interactions. His other odd behaviors—such as avoidance of eye contact, lack of social interest in his siblings, and extreme preoccupation with his ball—are best accounted for by autism. Table 14.5 provides additional facts about autism.

What Is Asperger’s Disorder?

A disorder related to autism, but less severe, is **Asperger’s disorder** (also referred to as *Asperger’s syndrome*, or simply, *Asperger’s*), which involves similar types of problems with social interaction and narrowed behaviors. However, unlike individuals with autism, the diagnostic criteria specify that those with Asperger’s have language and cognitive abilities that are within the normal range—and so mental retardation cannot be present.

Children with Asperger’s disorder often have problems with the relatively subtle social cues related to language—the indirect or implied meanings behind words. For instance, someone with Asperger’s might interpret “I’d

Asperger’s disorder

A psychological disorder on the autism spectrum characterized by problems with social interaction and narrowed behaviors—similar to but less severe than autism—but in which language and cognitive development are in the normal range; also referred to as *Asperger’s syndrome*.

Table 14.5 ▶ Autistic Disorder Facts at a Glance

Prevalence

- Significantly less than 1% of the population has this disorder; prevalence estimates range from 0.02% to 0.2%.
- The reported prevalence of autism is increasing (Atladóttir, 2007; Hertz-Picciotto & Delwiche, 2009), at least in part because of earlier diagnosis of the disorder (Parner, Schendel, & Thorsen, 2008).

Onset

- Symptoms usually arise during infancy and include an indifference or aversion to physical contact, no eye contact or smiles, a lack of response to parents’ voices, a lack of emotional attachment to parents, and the unusual use of toys (Ozonoff et al., 2008).
- According to the DSM-IV-TR criteria, symptoms must arise by age 3.
- Autism may be diagnosed as early as 14 months of age (Landa, Holman, & Garrett-Mayer, 2007).

Comorbidity

- Mental retardation is a common comorbid disorder—between 50% and 70% of those with autism also have mental retardation (Sigman, Spence, & Wang, 2006). However, some researchers believe the high comorbidity is an overestimate (Edelson, 2006), particularly because individuals with autism tend to have higher IQs when tested using nonverbal IQ tests.
- Some researchers make a distinction between autism that co-occurs with mental retardation, which leads to a relatively low level of functioning, and autism without mental retardation, which is not generally associated with as low a level of functioning (Koyama et al., 2007).

Course

- Children with autism often improve in some areas of functioning during the elementary school years (Shattuck et al., 2007).
- During adolescence, some children’s symptoms worsen, whereas other children’s symptoms improve (American Psychiatric Association, 2000; Shattuck et al., 2007).

Gender Differences

- Males are four to five times more likely than females to develop autism.

like to borrow that” not as a request to borrow the object but simply as an expressed wish. Table 14.6 lists the complete diagnostic criteria.

People with Asperger's often avoid sustained eye contact, and don't use other nonverbal behaviors, such as facial expressions or body language, in normal ways (Criterion A1). And because they don't understand social conventions, their behavior can (inadvertently) communicate disinterest in others. Whereas autism is characterized by an indifference to others, Asperger's tends to involve a lack of awareness of other people's *responses*. For example, someone with Asperger's may continue talking about a topic long past the point at which the listener's interest has waned. The person with Asperger's doesn't notice—doesn't pick up on the social cues that indicate that the other person is no longer listening.

To be diagnosed with Asperger's, the individual must have symptoms that impair the ability to function at school and care for himself or herself. Unlike those with autism, however, children with Asperger's develop in all areas (including language) except social functioning. In fact, the disorder often isn't diagnosed in early childhood because all other areas of functioning are relatively normal. DSM-IV-TR includes Asperger's disorder in the category of pervasive developmental disorders in order to group it with autism. However, Asperger's does *not* involve pervasive deficits. Table 14.7 provides additional facts about this disorder.

Like people with autism, people with Asperger's often develop an all-consuming but narrow interest, spending large amounts of time on it, to the point of neglecting other activities. Josh, described in Case 14.3, has a consuming passion about directions.

CASE 14.3 ► FROM THE OUTSIDE: Asperger's Disorder

Josh is described by his older brother Ryan, a college student.

Josh, a lot of the times is to himself [sic]. He's off to the side, he likes to be in his own little world. And he's got kind of . . . I want to say, a downward pull, he wants to think that everyone wants to threaten him. For the longest time I'd yell at him because I'd say, "Stop crying, why are you crying? There's no need to cry. I didn't say anything!" But to him, it's a threat if you say something and . . . he can't control the way he feels. . . .

. . . when he needs his time, you give him his time. And when he's ready to come out and be social again, then he'll come out.

And I try my best to introduce him to all the people that I know so he doesn't feel uncomfortable and alone.

. . . when he's doing something that he wants to learn about or that he's interested in or that I've done, he's extraordinarily lively. He's very happy. And that's when he gets to his loud stages where he'll laugh and he's way up there. I love to see him laugh, but when something is funny he is, horrendously loud, he's over the top . . . sometimes I'll take his hand and I'll give him a little squeeze on the hand and that's kind of his cue to kind of like ease it down a little bit.

Josh is amazing at directions . . . he can give directions to anybody to anything, if you are anywhere in the US, he'll tell you where you are. . . . I get lost all the time, directions are not my thing and . . . I'll call Josh, now . . . when like, I'm out on the road. . . . I'm like "Josh, I don't know where I'm at" and he'll say like, "What's around you?" and I'll tell him and he'll know exactly where I am. It's really cool.

(Coulter, 2007)

Josh is not aware when he is too loud, because he isn't able to read other people's nonverbal signals appropriately. Such social communication problems can lead to depression and anxiety in people with Asperger's: They are unable to understand and respond to others appropriately and thus may be rejected or ridiculed (Meyer et al., 2006). Their problems in understanding social cues can also lead to difficulty in feeling empathy (Lawson, Baron-Cohen, & Wheelwright, 2004).

People with Asperger's often fall into one of two social patterns: (1) They become socially isolated, minimizing contact with others (they are similar to people with autism in this regard); or (2) they become socially annoying, seeking out interactions with others but, because of their limited social skills, imposing their desires on others. Children with Asperger's often do best socially when interacting either with adults (who are more tolerant of their social foibles) or with younger children, who are willing to be bossed around by an older child (Kundert & Trimarchi, 2006).

Distinguishing Between Asperger's Disorder and Other Disorders

Asperger's disorder can sometimes be difficult to distinguish from other disorders, particularly autism without comorbid mental retardation. However, two factors typically arise in autism but not in Asperger's disorder:

1. language problems in addition to social difficulties, and
2. extreme distress when change is foisted upon them.

Even in the area of social functioning there can be differences: An individual with autism is often uninterested in social interactions, whereas an individual with Asperger's may be interested but does not possess the social skills necessary for smooth interactions.

Some symptoms of Asperger's disorder overlap with those of schizoid personality disorder (Chapter 13): Both disorders involve a lack of close friendships and a preference for solitary activities. However, older children and adolescents with Asperger's are more interested in social interactions and relationships than are people with schizoid personality disorder.

People with Asperger's are distinguished from those with normal social awkwardness by their difficulty in understanding social cues. Furthermore, the all-consuming

Table 14.7 ► Asperger's Disorder Facts at a Glance

Prevalence

- The estimated prevalence for Asperger's disorder is around 0.25–0.8% (Fombonne, 2005; Ozonoff, Rogers, & Hendren, 2003), depending on the exact criteria used, the research methods used, and the population studied.

Onset

- Although symptoms may emerge during early childhood, Asperger's is often not diagnosed until the child is in elementary or middle school because academic performance is normal. In some cases, the child's difficulty in social situations is not understood as a deficit but viewed as willful behavior.

Comorbidity

- Depression and anxiety disorders are the most common comorbid disorders. Attention-deficit/hyperactivity disorder may also co-occur.
- Asperger's is the only pervasive developmental disorder that cannot be comorbid with mental retardation—the DSM-IV-TR criteria stipulate normal cognitive development.

Course

- As children with Asperger's disorder enter adolescence and adulthood they may become aware of their social difficulties and isolation; this awareness may contribute to comorbid depression. However, many children with Asperger's are able to improve their social skills.
- Asperger's disorder has a good prognosis, and the higher the individual's IQ, the better the prognosis. Most people with Asperger's are able to work and be self-sufficient.

Gender Differences

- At least five times more males than females are diagnosed with Asperger's disorder.

Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

focus on a narrow interest is different from a normal “passion” for a hobby or activity in that people with Asperger’s have significant difficulty putting aside their interest to attend to necessary tasks, such as eating and going to school.

Understanding Autism Spectrum Disorders

Let’s examine the factors that give rise to the autism spectrum disorders (autism and Asperger’s). Autism is the pervasive developmental disorder that has been the most widely investigated (and, as noted in Table 14.5, the prevalence rate is increasing), whereas the factors that give rise to Asperger’s disorder have only recently been the focus of study. Therefore, most of the discussion that follows pertains to autism, unless otherwise noted.

Autism appears to be rooted primarily in neurological factors, which interact with psychological and social factors. The symptoms themselves involve a range of psychological and social factors.

Neurological Factors

Like schizophrenia, autism is marked by significant abnormalities in brain structure and function. Genetics also appears to play a role in this disorder.

Brain Systems Children who have autism have an unusually large head circumference, which is probably due to an above-average increase in white and gray matter during infancy (Hardan et al., 2006). However, adults with autism do not have larger than average heads, so the early accelerated growth is followed by slower growth during childhood (Herbert, 2005).

The connections and communication among brain areas also appear abnormal in autism (Minshew & Williams, 2007). Brain areas in the same region appear to communicate excessively, while there is too little communication among distant areas (Courchesne & Pierce 2005), in particular, between the frontal lobes and other brain areas (Murias et al., 2006). In addition, parts of the frontal lobe are less active among those with autism than among control group participants, which is consistent with the deficits in executive function that have been documented in autism (Silk et al., 2006). Asperger’s is associated with a variety of problems with motor coordination, which suggests abnormalities in the central nervous system; these coordination problems continue into adulthood (Tani et al., 2006) and are also seen in people with high-functioning autism (Jansiewicz et al., 2006).

Genetics How might these abnormalities arise? Genes appear to play a role. Researchers have long observed that autism tends to run in families; 8% of siblings of affected children will also have the disorder (compared to at most 0.2% of the general population; Muhle, Trentacoste, & Rapin, 2004). Even stronger evidence comes from twin studies: Monozygotic twin-pairs are up to nine times more likely to have the disorder than are dizygotic twin pairs (Bailey et al., 1995; Folstein & Rutter, 1977; Le Couteur et al., 1996; Steffenburg et al., 1989).

However, researchers have not located a single gene that always gives rise to autism (Weiss et al., 2008). Instead, most forms of autism probably arise from interactions among genes—perhaps 15 or more of them (Santangelo & Tsatsanis, 2005). Research suggests that one possible cause of the genetic mutations associated with some cases of autism is the father’s age at conception (Croen et al., 2007): Fathers who were 40 or older were almost six times more likely to have children with autism than fathers younger than 30 (Reichenberg et al., 2006). Older mothers were also more likely to have children with an autism spectrum disorder (Croen et al., 2007).

Certain stimuli may trigger autism in genetically vulnerable children (Waldman et al., 2008). Although researchers had earlier suggested that the cause of autism might be *thimerisol*, an ingredient in a widely used vaccine for measles-mumps-rubella, no studies have so far been able to document a causal link between this vaccine and the disorder (Muhle, Trentacoste, & Rapin, 2004; Thompson et al., 2007). In fact, autism rates continue to increase even among children who received vaccines without thimerisol (Schechter & Grether, 2008), which indicates that factors other than thimerisol are at work. Another possibility was suggested by the

discovery that in 2005 more children had autism in counties of the Northwest states (California, Oregon, and Washington) that had more days of rain from 1987 to 2001. The researchers conjectured that bad weather may lead children to spend more time indoors, possibly increasing their television viewing, their risk for a vitamin D deficiency, or their exposure to household cleaning products.

Like autism, Asperger's disorder appears to have a genetic basis: Compared to the general population, relatives of someone with Asperger's are more likely to have an autism spectrum disorder (Cederlund & Gillberg, 2004).

Psychological Factors: Cognitive Deficits

Neurological factors give rise to psychological symptoms, particularly cognitive deficits in shifting attention and in mental flexibility (Ozonoff & Jensen, 1999). These deficits underlie the extreme difficulty in transitioning from one activity to another that individuals with autism spectrum disorders experience; people with autism also tend to focus on details at the expense of the broader picture (Frith, 2003). However, these deficits are not part of the DSM-IV-TR diagnostic criteria.

Another problem—also not noted in the DSM-IV-TR criteria—is difficulty in recognizing facial expressions of emotions (Serra et al., 2003). For example, in one study 3- and 4-year-olds' brain activity was assessed with EEG while they were shown photographs of faces that either expressed fear or had neutral expressions. Normal children exhibited greater brain activity in response to the fear expressions than to the neutral expressions. But children with autism responded to both types of facial expressions with the same pattern of brain activity (Dawson et al., 2004).

People with autism also have difficulty viewing the world from another person's perspective—with using a **theory of mind**, which is a theory about other people's mental states (their beliefs, desires, and feelings) that allows each of us to predict how others will react in a given situation (Tager-Flusberg, 1999). Because a theory of mind requires thinking about somebody else, by definition, this ability involves both psychological and social factors. An impaired theory of mind is demonstrated with the *false belief test* (Baron-Cohen, Leslie, & Frith, 1985), which requires that the participant keep in mind the point of view of someone else: Two dolls, Sally and Anne, are used to act out a scene. Sally puts a marble in a basket and then leaves the room without taking the basket. Anne then quietly moves the marble from the basket into a box. The child is then asked to say where Sally will look for the marble when she comes back in the room. The correct answer, that Sally will look in the basket, requires the participant to appreciate the point of view of Sally, who does not know that the marble was moved. In this study, 80% of the children with autism answered incorrectly that Sally would look in the box. These children were not able to override what they knew and take Sally's perspective. Although some individuals with milder symptoms of autism may be able to answer correctly on the false belief test, they are not able to do so when the task involves more complex processing of social cues, such as understanding white lies or irony (Happé, 1994).

People with Asperger's disorder also have an impaired theory of mind. However, these problems are less severe than in people with autism (Ziatas, Durkin, & Pratt, 2003). In addition, even the normal siblings of individuals with Asperger's have an impaired theory of mind (Dorris et al., 2004), which provides further support for the inference that genes play a role in this disorder.

Social Factors: Communication Problems

The earliest indications of autism arise in interactions with other people: Children with autism pay attention to other people's mouths, not their eyes (Dawson, Webb, & McPartland, 2005) and don't respond to their own name or to parents' voices (Baranek, 1999). Moreover, they don't develop normal communication skills—verbal or nonverbal. As they get older, they don't develop the typical ability to recognize faces, and they also have problems recognizing emotion, both in voices (Rutherford, Baron-Cohen, & Wheelwright, 2002) and in facial expressions (Bölte & Poustka, 2003). These cognitive deficits make social interactions confusing and unpredictable.

Theory of mind

A theory about other people's mental states (their beliefs, desires, and feelings) that allows a person to predict how other people will react in a given situation.

Even older children with autism who have developed some communication skills may still have deficits that prevent normal conversation. And, despite adequate verbal skills, adults with autism often don't understand elements of conversation involving a back-and-forth exchange of information and interest in the other person, and so cannot interact normally.

Asperger's disorder involves similar—although less severe—problems with social communication. However, there is very little research on how various factors might contribute to autism as compared to Asperger's disorder.

In sum, autism and Asperger's disorder are primarily caused by neurological factors (including those that are consequences of genetics); the neurological factors give rise to symptoms of the disorder, which are psychological and social in nature. As noted earlier, psychological and social factors also influence the course of these disorders—indeed, every social interaction has the potential to change the brain, if only by inducing learning (which occurs because of neural changes). However, at present, it appears that psychological and social factors contribute to autism and Asperger's disorder only indirectly (e.g., by influencing where a person lives, which in turn may be a risk factor for exposure to certain stimuli). For this reason, in this section we do not discuss feedback loops for autism spectrum disorders.

Treating Autism Spectrum Disorders

Treatment of autism generally focuses on increasing communication skills and appropriate social behaviors. Unfortunately, there is no cure for autism, and no one type of intervention is helpful for all those with the disorder. The treatments that are most effective are time-intensive (at least 25 hours per week), have strong family involvement, are individualized to the child, and begin as early in the child's life as possible (Rogers, 1998). Early treatment depends on early diagnosis of the disorder; to ensure early diagnosis, the American Academy of Pediatrics recommends that all children receive screening tests for autism before the age of 2 (Johnson, Meyers, & Council on Children with Disabilities, 2007).

Targeting Neurological Factors

No treatments successfully target the neurological factors that appear to underlie autism spectrum disorders. Medication may help treat symptoms of comorbid disorders or of agitation or aggression. The medications most likely to be prescribed are antipsychotics and selective serotonin-reuptake inhibitors (SSRIs; des Portes, Hagerman, & Hendern, 2003). Some research suggests that people with autism may be more likely than other people to experience side effects from medications (Harden & Lubetsky, 2005). Medication is not usually prescribed for people with Asperger's disorder (Campbell & Morgan, 1998), unless it is for a comorbid disorder.

Targeting Psychological Factors: Applied Behavior Analysis

The technique most widely used to modify the maladaptive behaviors associated with autism is called **applied behavior analysis**. This method uses shaping (described in Chapter 4) to help individuals learn complex behaviors. The key idea is that a complex behavior is divided into short, simple actions that are reinforced and then ultimately strung together. For example, many children with autism eat with their hands and resist eating with utensils, which can create problems when eating with classmates or when the family goes out to eat. Thus, learning to use a spoon is one behavior that is often shaped via applied behavior analysis. Initially, the therapist looks for any spoon-related behavior—such as a glance at the spoon or the child's moving a hand near the spoon—and responds with verbal reinforcement (“That’s right, there is the spoon, good job”) and perhaps some concrete reward, such as a few small candies. After a few successful attempts at approaching the spoon, the child is reinforced for picking up the spoon, then for putting the spoon

AP Photo/The Daily Messenger, Eric Sucar

Jason McElwain, at 17, was manager of his high school's basketball team; he was thought to be too small to be on the team. At the final home game, which his team was losing, with 4 minutes to go, he was allowed to play. Here he is being cheered by his teammates and the crowd after he went on to score 20 points and win the game. Jason was diagnosed with autism when he was 2 years old; he didn't begin speaking until he was 5 years old (Associated Press, 2006). As he grew older his social skills improved (McElwain & Paisner, 2008).

Applied behavior analysis

A technique used to modify maladaptive behaviors by reinforcing new behaviors through shaping.

in the mouth, and finally for using it with food. Parents of children with autism are encouraged to use this method at home.

Targeting Social Factors: Communication

Treatment for autism and Asperger's disorder that addresses social factors often focuses, in one way or another, on facilitating communication and interpersonal interactions. For example, when an individual with autism has severe communication difficulties, treatment may include the use of PECS, the picture system for facilitating communication mentioned in the section on mental retardation. For people with high-functioning autism or Asperger's, treatment may focus on training appropriate social behaviors through social skills groups or through individual instruction and modeling—observing others engaging in appropriate social behavior and then role-playing such behaviors (Bock, 2007). For instance, when Richie enters elementary school, he might attend a social skills group for selected kindergarteners and first-graders; the psychologist who leads such groups explicitly teaches the children appropriate social behavior—such as making eye contact and asking and answering questions—and has the children practice with each other. Parents are asked to continue social skills training at home by modeling desired social behaviors and reinforcing their children for improved behavior (Kransny et al., 2003).

In addition, various training programs have been developed to help people with Asperger's or autism who do not also have mental retardation; such programs help them perceive and interpret social cues—facial expressions and body language—more accurately. In fact, there is a pilot project that uses a computer game to provide such training (Golan & Baron-Cohen, 2006). Another tool to develop the ability to read social cues is social stories, which are stories in which the important social cues and responses are made explicit (Konstantareas, 2006). Although intriguing, research on the outcomes of various training programs and their tools is in its infancy. The extent to which a change in one factor affects another factor is unknown for the autism spectrum disorders. Thus, we do not include a discussion of treatment-related feedback loops among the three types of factors.

Other Pervasive Developmental Disorders

DSM-IV-TR includes two other disorders in the subcategory of pervasive developmental disorders: *childhood disintegrative disorder* and *Rett's disorder*. Both disorders are extremely rare, and are caused by neurological factors.

Childhood Disintegrative Disorder

In contrast to autism, which involves deficits in communication and interest in others since birth, **childhood disintegrative disorder** is characterized by normal development until at least 2 years old, followed by a profound loss of communication skills, normal types of play, and bowel control. The loss of normal functioning may occur as early as 2 years old or as late as 10 years old. DSM-IV-TR requires a loss of skills in at least two of five areas: language, social skills, bowel or bladder control, play, and motor skills. Normal functioning is often lost in all five areas (American Psychiatric Association, 2000). Thus, a clinician can distinguish childhood disintegrative disorder from autism by the age of the child when the symptoms began and by the course of the symptoms: Symptoms of childhood disintegrative disorder usually do not improve over time (Ozonoff, Rogers, & Hendren, 2003), whereas symptoms of autism can improve with interventions. Childhood disintegrative disorder is a rare neurological disorder that is caused by factors that appear to be unrelated to those of autism.

Rett's Disorder

Similar to childhood disintegrative disorder, Rett's disorder—which afflicts only females—involves a loss of skills already mastered. Specifically, **Rett's disorder** is characterized by normal prenatal development and normal functioning after birth through at least 5 months of age (up to about 2 years), after which the growth of

Childhood disintegrative disorder

A pervasive developmental disorder characterized by normal development until at least 2 years old, followed by a profound loss of communication skills, normal types of play, and bowel control.

Rett's disorder

A pervasive developmental disorder that affects only females and is characterized by normal prenatal development and functioning after birth through at least 5 months of age, after which the growth of the child's head slows and she loses the ability to control normal muscle movements, interest in other people, and previously developed skills.

the girl's head slows and she loses the ability to control normal muscle movements, interest in other people, and previously developed skills. The skills that are lost include the voluntary movement of hands (which is replaced by recurrent hand gestures that resemble hand-washing or hand-wringing) and coordination of the trunk. In addition to the loss of skills, a girl with Rett's disorder has language problems and psychomotor retardation. Mental retardation is an inevitable consequence of this disorder.

Although Rett's disorder includes some of the problems in communicating that mark autism and childhood disintegrative disorder, it has three unique features: a slowed rate of growth of the child's head circumference, coordination problems, and the loss of hand skills. Moreover, symptoms of Rett's disorder emerge by 2 years of age, at the latest; childhood disintegrative disorder symptoms emerge between 2 and 10. Rett's disorder occurs only in females because it is an X-linked genetic disorder that impedes normal brain development related to movement and cognition (Amir et al., 1999; Matijevic et al., 2009). Male fetuses with this mutation typically do not survive until birth.

Key Concepts and Facts About Pervasive Developmental Disorders

- Pervasive developmental disorders involve two types of problems: (1) significant deficits in communication and social interaction skills, and (2) stereotyped behaviors or narrow interests. Disorders in this category are autistic disorder, Asperger's disorder, childhood disintegrative disorder, and Rett's disorder.
- Autistic disorder (or simply, autism) is characterized by significant problems with communication, social interactions, and language use. Individuals with autism are oblivious to other people and do not pay attention to or understand basic social rules and cues. They may have extremely narrow interests involving repetitive play. Many people with autism also have comorbid mental retardation when tested with conventional intelligence tests; on tests that do not rely on verbal abilities, however, people with autism tend to score in the average range or higher. In addition, some people with autism have unique skills.
- Asperger's disorder is characterized by problems that are similar to—though less severe than—those associated with autism. With Asperger's, however, language and cognitive development are in the normal range. People with Asperger's avoid eye contact and are often unaware of other people's responses. They may be interested in social relationships but because they do not generally understand conventional social rules, forming and maintaining relationships is difficult.
- Neurological factors that underlie autism include abnormal connections and communication among different brain areas, in particular, between the frontal lobe and the rest of the brain. Genes play a role in the development of autism and Asperger's.
- Psychological symptoms of autism include deficits in shifting attention and in mental flexibility, and an impaired theory of mind. People with Asperger's have less severe problems in using a theory of mind than do people with autism. Social symptoms of autism include problems in recognizing emotion in the voices or faces of others and in understanding the give and take of social communication.
- Interventions for autism include medication for comorbid disorders or symptoms of anxiety, agitation, and aggression. Medication is not usually prescribed for symptoms of Asperger's disorder. Treatment for autism that targets psychological factors includes applied behavior analysis to modify maladaptive behaviors. Treatments that target psychological and social factors focus on teaching the individual to communicate, to recognize conventional social cues, and to read the emotional expressions of others, as well as how to initiate and respond in social situations.
- In contrast to autism and Asperger's disorder, childhood disintegrative disorder is characterized by normal development up to at least 2 years of age, followed by a profound loss of communication skills, normal types of play, and bowel control.
- Rett's disorder also involves the loss of skills already mastered, but the onset of the disorder occurs between 5 months and 2 years of age. The child loses interest in other people and the ability to control normal muscle movements. Mental retardation always accompanies Rett's disorder, which affects only females.

Making a Diagnosis

- Reread Case 14.2 about James, and determine whether or not his symptoms meet the criteria for autism. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 14.3 about Josh, and determine whether or not his symptoms meet the criteria for Asperger's disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Learning Disorders: Problems with the Three Rs

Richie Enriquez’s older brother, Javier, is in the 4th grade. Javier’s teacher has noted that his reading ability doesn’t seem up to what it should be. Javier is a bright boy, but when the students take turns reading aloud, Javier isn’t able to read as well as his classmates. Javier generally has things he wants to say in class—sometimes raising his hand so high and waving it so energetically that he practically hits the heads of nearby children; his comments often show a keen understanding of what the teacher has said. His apparent reading problem seems to be at odds with his general intelligence. Could Javier have a learning disorder?

What Are Learning Disorders?

A **learning disorder** is characterized by a significant disparity between an individual’s academic performance and the expected level of performance based on the individual’s age, intelligence (assessed through an IQ test), and education level. Achievement that is at least two standard deviations below the level of a person’s IQ score is the general guideline for diagnosing learning disorders. However, a gap less than that may be applicable when a comorbid anxiety disorder interferes with performance on an IQ test or when an individual’s ethnic or cultural background decreases his or her familiarity with the items on the IQ test. DSM-IV-TR specifies three types of learning disorders: *reading*, *mathematics*, and *written expression*. The reading disorder is also referred to as **dyslexia**. Table 14.8 lists the DSM-IV-TR criteria for learning disorders generally.

Table 14.8 ▶ DSM-IV-TR Diagnostic Criteria for Learning Disorders

- | |
|---|
| A. The specific ability, as measured by individually administered standardized tests, is substantially below that expected given the person’s chronological age, measured intelligence, and age-appropriate education. |
| B. The disturbance in Criterion A significantly interferes with academic achievement or activities of daily living that require reading skills. |
| C. If a sensory deficit is present, the learning difficulties are in excess of those usually associated with the sensory deficit. |

Source: Adapted from American Psychiatric Association, 2000.

DSM-IV-TR lists specific deficits for each type of learning disorder (American Psychiatric Association, 2000):

- *Reading disorder* is characterized by difficulty with reading accuracy, speed, or comprehension, to the point that the difficulty interferes with academic achievement or activities of daily functioning that involve reading.
- *Mathematics disorder* is characterized by difficulty with recognizing numbers or symbols, paying attention to and remembering all the different steps in a math problem, particular arithmetic skills such as multiplication, or translating written problems into arithmetic symbols.
- *Disorder of written expression* is diagnosed when poor spelling or handwriting occurs *along with* significant grammatical or punctuation mistakes or problems in paragraph organization. (This is the least studied of the learning disorders.)

Nancy, in Case 14.4, has a reading disorder. Additional facts about learning disorders are presented in Table 14.9.

Learning disorder

A psychological disorder characterized by a significant disparity between an individual’s academic performance and the expected level of performance based on his or her age, intelligence, and education level.

Dyslexia

A learning disorder characterized by difficulty with reading accuracy, speed, or comprehension that interferes with academic achievement or activities of daily functioning that involve reading.

**Table 14.9 ▶ Learning Disorders
Facts at a Glance****Prevalence**

- Between 2% and 10% of Americans are estimated to have a learning disorder.
- Five percent of public school students in the United States are diagnosed with a learning disorder.

Onset

- Symptoms of learning disorders do not usually emerge until early in elementary school (typically kindergarten through 3rd grade), when the relevant academic skills are needed.
- Children with a high IQ and a reading or mathematics disorder may not be diagnosed until the 4th grade or later.
- Symptoms appear rapidly when they arise from a serious medical problem.

Comorbidity

- Common comorbid disorders include depressive disorders and attention-deficit/hyperactivity disorder.
- Mathematics disorder and written expression disorder commonly co-occur with reading disorder.

Course

- With early identification and intervention, a significant number of children with reading disorder can overcome their difficulties.

Gender Differences

- Between 60% and 80% of people with reading disorder are male; however, males may be more likely to be diagnosed because of their disruptive behavior, which calls attention to their difficulties.

Cultural Differences

- In the United States, Hispanic children are least likely to be diagnosed with a learning disorder, perhaps because language barriers make it more difficult to diagnose (National Center for Health Statistics, 2008).

CASE 14.4 ▶ FROM THE INSIDE: Learning Disorder (Reading)

Nancy Lelewer, author of *Something's Not Right: One Family's Struggle With Learning Disabilities* (1994), describes what having a learning disorder was like for her:

I began public elementary school in the early 1940s. . . . Reading was taught exclusively by a whole-word method dubbed "Look, Say" because of its reliance on recognizing individual words as whole visual patterns, rather than focusing on letters or letter patterns. In first grade, I listened to my classmates, and when it was my turn, I read the pictures, not the words, "Oh Sally! See Spot. Run. Run. Run." When we were shown flash cards and responded in unison to them, I mouthed something.

Then came our first reading test. The teacher handed each student a sheet of paper, the top half of which was covered with writing. I looked at it and couldn't read a word. . . . The room grew quiet as the class began to read.

As I stared at the page, total panic gripped me. My insides churned, and I began to perspire as I wondered what I was going to do. As it happened, the boy who sat right in front of me was the most able reader in my class. Within a few minutes, he had completed the test and had pushed his paper to the front of his desk, which put it in my full view. . . . [I copied his answers and] passed the test and was off on a track of living by my wits rather than being able to read.

The "wits track" is a nerve-wracking one. I worried that the boy would be out sick on the day we had a reading test. I worried that the teacher might change the location of my desk. I worried that I would get caught copying another student's answers. I knew that something was wrong with me, but I didn't know what. Why couldn't I recognize words that my classmates read so easily? Because everyone praised me when I did well on tests, I did my best to hide my inadequate reading skills. (pp. 15–17)

Unfortunately, learning disorders may cast a long shadow over many areas of life for many years. People with learning disorders are 50% more likely to drop out of school than are other people in the general population, and work and social relationships are also more likely to suffer (American Psychiatric Association, 2000). They are also more likely to suffer from poor self-esteem.

Social factors can lead a child to be incorrectly diagnosed with a learning disorder. For example, immigrant children may not have English language skills advanced enough to allow their reading, writing, or math skills to approach the expected level of performance. Children who have frequently been absent from school may also be incorrectly diagnosed with a learning disorder—the problem may simply be that they missed so much school that they didn't receive adequate instruction in those skills. At Javier's school, when a teacher thinks that a child may have a learning disorder, the relevant staff members meet: The teacher, the school learning specialist, the speech and language therapist, and the school psychologist discuss the teacher's concerns and decide what steps should be taken. These next steps may include observing the child in the classroom, recommending a formal evaluation, and/or talking with the parents.

Understanding Learning Disorders

Like mental retardation and pervasive developmental disorders, learning disorders arise in large part because of neurological factors. But psychological and social factors also play a role.

Neurological Factors

Among the three types of learning disorders, dyslexia has been studied the most extensively. Evidence is growing that impaired brain systems underlie this disorder and that genes contribute to these impaired systems.

Brain Systems

In most forms of dyslexia, the brain systems involved in auditory processing do not function as they should (Marshall et al., 2008; Ramus et al., 2003). For example, one study used electrodes placed on the scalp to examine the brain waves of infants while they listened to syllables coming out of a speaker. Eight years later, the children's reading abilities were assessed, and the children classified as dyslexic, poor readers, or normal readers. The children who were classified as dyslexic at 8 years old had brain-wave patterns in infancy (while they listened to spoken syllables) that were different from those of the children whose reading ability was classified as normal, which suggests that the children with dyslexia were born with processing problems in the auditory system (Molfese, 2000). Further research has suggested that these brain-wave differences continue at least through the first 4 years of life (Espy et al. 2004).

The results of many neuroimaging studies have converged to identify a set of brain areas that is disrupted in people who have dyslexia (Shaywitz, Lyon, & Shaywitz, 2006). First, two rear areas in the left hemisphere are not as strongly activated during reading tasks in people with dyslexia as they are in people who read normally. One of these areas, at the junction of the parietal and temporal lobes, appears to be involved in converting visual input to sounds (Friedman, Ween, & Albert, 1993). The other area, at the junction of the parietal and occipital lobes, appears to be used to recognize whole words, based on their visual forms (Cao et al., 2006; McCandliss, Cohen, & Dehaene, 2003). Moreover, these areas are not activated normally even in young children with dyslexia, and thus the malfunction observed in adults cannot be a result of not reading properly over the course of many years but probably contributes to reading disorder (Shaywitz et al., 2002). Second, two other brain areas (the bottom part of the frontal lobe and the right occipital-temporal region) are more activated in people with a reading disorder than in people who read normally. These areas appear to be used in carrying out compensatory strategies, which rely on stored information instead of the usual vision-sound conversion process.

Consistent with the neuroimaging results, researchers have also reported structural differences between the brains of people with dyslexia and normal readers. Compared to people who read normally, people with dyslexia have reduced gray matter (which includes the cell bodies of neurons) in the temporal lobes, particularly the left temporal lobe (Vinckenbosch, Robichon, & Eliez, 2005), and portions of their frontal lobes are relatively large (Vinckenbosch, Robichon, & Eliez, 2005; Zadina et al., 2006). Moreover, people who have relatively large occipital lobes (which are specialized for vision) tend to read better than those with smaller occipital lobes (Zadina et al., 2006); this difference may suggest that at least some people with dyslexia have impaired visual abilities. (Fine et al., 2007).

However, the precise brain areas involved in dyslexia are influenced by culture, as manifested by the language spoken in a society. Specifically, part of the left frontal lobe is impaired in dyslexic children who speak Chinese, instead of the areas just discussed (which were assessed in English-speaking children). Chinese writing does not depend on an alphabet, but instead requires memorizing specific characters that correspond to words (Siok et al., 2004). The frontal lobes are involved in using stored information to help register current stimuli, and such processing may play a large role in reading Chinese characters.

At least some forms of dyslexia also appear to reflect a specific problem in processing visual stimuli—independent of problems in connecting those stimuli to sounds—which may be why some people with dyslexia reverse letters when they write (Vidyasagar, 2005). Thus, findings regarding brain systems suggest that there are probably different forms of dyslexia, with different underlying causes.

Genetics

Reading disorder, and possibly the other learning disorders, are moderately to highly heritable (Hawke, Wadsworth, & DeFries, 2006; Schulte-Körne, 2001), and at least four specific genes are thought to affect the development of these disorders

(Fisher & Francks, 2006; Marino et al., 2007). Some of these genes affect how neurons are connected during brain development (Rosen et al., 2007), and some may affect the functioning of neurons or influence the activity of neurotransmitters (Grigorenko, 2001).

However, there is evidence that environmental factors—such as attending a low-quality school or coming from a disadvantaged family—can contribute to at least some forms of dyslexia (Olson et al., 1999; Shaywitz, Lyon, & Shaywitz, 2006; Wadsworth et al., 2000).

Psychological Factors

Although learning disorders arise from neurological abnormalities, this is not the end of the story. Some children with learning disorders succeed in situations where others fail. Why? In order to address this question, researchers interviewed college students with learning disorders and specifically asked about their experiences as young children (Miller, 2002). These people reported a number of psychological factors that played important roles in shaping their *motivation* to overcome their disorder; these factors included success experiences, self-determination, recognizing particular areas of strength, identifying the learning disability, and developing ways to cope with it. One person recounted, “I like to do things on my own, and if I [I’m] going to learn it, I’m going to keep drilling myself and doing it on my own . . . until it sinks in” (Miller, 2002, p. 295).

Social Factors

Social factors play a role in shaping motivation to persist in the face of difficulties (Miller, 2002). Other people, such as parents and teachers, were important in supporting and encouraging children who later succeeded in overcoming their learning disabilities. Social factors such as support and encouragement can thus affect a psychological factor—motivation to persist despite problems with learning. However, it is not clear whether the various factors—neurological, psychological, and social—have other interactions via feedback loops.

In sum, research findings suggest that impaired brain systems underlie learning disorders. Dyslexia—the most extensively studied learning disorder—appears to involve problems in the brain systems that process language and in brain systems that process visual stimuli. However, other factors also affect the nature and course of the disorder: Motivation and social support influence an individual’s ability to overcome and compensate for a learning disorder.

Treating Learning Disorders

Children with learning disorders are eligible for the accommodations and services mandated by the Individuals with Disabilities Education Act (IDEA), as described earlier. As with the other childhood disorders discussed thus far in this chapter, neurological factors are generally not directly targeted for treatment (unless the treatment is for a comorbid disorder). Dyslexia has been the subject of the most research on treatment, and researchers have reported successful interventions for this disorder.

Treating Dyslexia

Some techniques for helping people with dyslexia include phonological practice, which consists of learning to divide words into individual sounds and to identify rhyming words. Another technique focuses on teaching children the *alphabetic principle*, which governs the way in which letters signal elementary speech sounds (Shaywitz et al., 2004). In fact, various forms of training using these techniques have been shown not only to improve performance but also to improve the functioning of brain areas that were impaired prior to the training (Gaab et al., 2007; Simos et al., 2007; Temple et al., 2003).

Treating Other Learning Disorders

Various techniques have been developed to help people cope with the other learning disorders. However, finding the most helpful technique for a given individual may be a trial-and-error process because numerous distinct problems can often underlie a deficit. In some cases, simply allowing an individual to have more time to complete a task can make a dramatic difference. In other cases, structuring the activity can help. For example, techniques to help people with mathematics disorder include the use of cue cards, breaking down the concepts into smaller steps, and giving immediate feedback for each step in a problem (Brosvic et al., 2006).

Unlike children with mental retardation and pervasive developmental disorders, children with a learning disorder and no comorbid disorder may not behave in a way that would cause them to be labeled as “different.” Although not being able to read well or do mathematical computations as well as peers can affect a child’s self-esteem and ability to succeed in several areas of life, it is also possible that a learning disorder may not influence other parts of life as strongly as mental retardation or autism generally do.

What do (left to right) singer Jewel, TV star Patrick Dempsey, martial artist Billy Blanks, business mogul Richard Branson, and actress Keira Knightley have in common? They all have dyslexia, which has not stopped them from attaining success in their fields.

Key Concepts and Facts About Learning Disorders

- A learning disorder is characterized by a substantial disparity between an individual's performance on a standardized test and the expected level of performance based on the individual's age, intelligence (assessed by an IQ test) and education level. DSM-IV-TR includes three types of learning disorders: reading disorder (dyslexia), mathematics disorder, and disorder of written expression.
- Genes contribute to learning disorders. Dyslexia appears to result from disruptions in brain systems that process language and in brain systems that process visual stimuli. Motivation and social support influence an individual's ability to overcome and compensate for a learning disorder.
- Treatment for learning disorders may involve accommodations and services mandated by the Individuals with Disabilities

Education Act (IDEA). Various cognitive techniques can help a person learn to compensate for a learning disorder. Depending on the specific learning disorder and the individual, some techniques may be more effective than others.

Making a Diagnosis

- Reread Case 14.4 about Nancy, and determine whether or not her symptoms meet the criteria for a learning disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Disorders of Disruptive Behavior and Attention

In addition to Javier Enriquez's apparent difficulties reading, his teacher has commented—not very positively—on Javier's high energy level. He doesn't always stay in his chair during class, and when he's working on a group project, other kids seem to get annoyed at him: "He can get 'in their face' a bit." Javier's mother, Lela, and his father, Carlos, acknowledge that Javier is a very active, energetic boy. But Carlos says, "I was that way when I was a kid, but I grew out of it as I got older." Javier's teacher recently mentioned the possibility of his having attention-deficit/hyperactivity disorder.

In contrast, Javier's sister, 8-year-old Pia, is definitely not energetic. Like her brother, Pia is clearly bright, but her teacher says she seems to "space out" in class. The teacher thinks that Pia is simply not applying herself, but her parents wonder whether she's underachieving because she's bored and understimulated in school. At home, Pia has defied her parents increasingly often—not doing her chores or performing simple tasks they ask her to do. Lela and Carlos then get frustrated and angry. At other times, Pia is off in her own world, "kind of like an absent-minded professor."

Hounding Pia to do her chores (and getting angry when she doesn't) is not a new pattern. For a number of years, her parents frequently had to remind Pia to clean up her room, make her bed, and help set the table. They thought she was intentionally defying them. Is Pia's behavior in the normal range, or does it signal a problem? If so, what might the problem be?

And what about Javier's behavior—is it in the normal range? Most children are disruptive some of the time. But in some cases, the disruptive behavior is much more frequent and obtrusive and becomes a cause for concern. The most common reason that children are referred to a clinician is because of disruptive behavior at home, at school, or both (Frick & Silverthorn, 2001). The clinician's task is to distinguish between normal behavior and pathologically disruptive behavior and, if the behavior falls outside the normal range, determine which disorder(s) might be the cause (Christophersen & Mortweet, 2001). The disruptive behaviors may not necessarily distress the individual who performs them. But the behaviors often distress other people or violate social norms (Christophersen & Mortweet, 2001).

Three disorders are associated with disruptive behavior: *conduct disorder*, *oppositional defiant disorder*, and *attention-deficit/hyperactivity disorder* (which is

characterized mainly by problems with attention but sometimes by disruptive behavior as well). As we'll see, symptoms of these three disorders commonly—though not always—occur together.

What Is Conduct Disorder?

The hallmark of **conduct disorder** is a violation of the basic rights of others or of societal norms that are appropriate to the individual's age (American Psychiatric Association, 2000). As outlined in Table 14.10, 15 types of behaviors are listed in the diagnostic criteria for conduct disorder; these behaviors are sorted into four categories:

- aggression to people and animals;
- destruction of property;
- deceitfulness or theft; and
- serious violation of rules.

Just as the criteria for antisocial personality disorder (Chapter 13) focus almost exclusively on behavior that violates the rights of others, so do the criteria for conduct disorder. To be diagnosed with antisocial personality disorder, the individual must be at least 18 years old. Although adults may be diagnosed with conduct disorder, it is most commonly diagnosed in children.

DSM-IV-TR requires the presence of a minimum of 3 out of the 15 types of behavior listed in Criterion A within the last 12 months; at least one type of behavior must have occurred during the last 6 months. Although the diagnosis requires impaired functioning in some area of life, it does *not* require distress.

Most individuals diagnosed with conduct disorder are under 18 years old; if the behaviors persist into adulthood, the individual usually meets the criteria for antisocial personality disorder; in some cases, however, an individual may not meet all the criteria for that disorder and so retains the diagnosis of conduct disorder.

Like people with antisocial personality disorder, people with conduct disorder appear to lack empathy and concern for others, and they don't exhibit genuine remorse for their misdeeds. In fact, when the intent of another person's behavior is ambiguous, an individual with conduct disorder is likely to (mis)attribute the other's motives as threatening or hostile and then feel justified in his or her own aggressive behavior. People with conduct disorder typically blame others for their inappropriate behaviors ("He made me do it"). And though appearing self-confident, some people with conduct disorder may, in fact, have low self-esteem; however, other people with this disorder have overinflated self-esteem. Outbursts of anger, recklessness, and poor frustration tolerance also frequently occur, although these characteristics are not part of the DSM-IV-TR criteria.

DSM-IV-TR specifies three levels of intensity for the symptoms of conduct disorder; the symptoms may progress from mildly disruptive to severely disruptive behaviors:

- *Mild*. The individual has only the minimum number of symptoms to meet the criteria, and the disruptive behaviors cause minimal harm to others (for example, lying or staying out after curfew).

Table 14.10 ▶ DSM-IV-TR Diagnostic Criteria for Conduct Disorder

A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of three (or more) of the following criteria in the past 12 months, with at least one criterion present in the past 6 months:

Aggression to people and animals

- (1) often bullies, threatens, or intimidates others;
- (2) often initiates physical fights;
- (3) has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun);
- (4) has been physically cruel to people;
- (5) has been physically cruel to animals;
- (6) has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery);
- (7) has forced someone into sexual activity.

Destruction of property

- (8) has deliberately engaged in fire setting with the intention of causing serious damage;
- (9) has deliberately destroyed others' property (other than by fire setting).

Deceitfulness or theft

- (10) has broken into someone else's house, building, or car;
- (11) often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others);
- (12) has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

Serious violations of rules

- (13) often stays out at night despite parental prohibitions, beginning before age 13 years;
- (14) has run away from home overnight at least twice while living in parental or parental surrogate home (or once without returning for a lengthy period);
- (15) is often truant from school, beginning before age 13 years.

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

C. If the individual is age 18 years or older, criteria are not met for Antisocial Personality Disorder [discussed in Chapter 13].

Conduct disorder

A psychological disorder that typically arises in childhood and is characterized by the violation of the basic rights of others or of societal norms that are appropriate to the individual's age.

- *Moderate.* The individual has a number of conduct problems, and their effect on other people is between mild and severe (for example, vandalism or stealing objects that were left unattended).
- *Severe.* The individual has many conduct problems, or the conduct problems create considerable harm to others (for example, forced sex, using a weapon, or stealing while confronting a victim).

People with conduct disorder are also likely to use—and abuse—substances at an earlier age than are people without this disorder. Similarly, they are more likely to have problems in school (such as suspension or expulsion), legal problems, unplanned pregnancies and sexually transmitted diseases, and physical injuries that result from fights. Because of their behavioral problems, children with conduct disorder may live in foster homes or attend special schools. They may also have poor academic achievement and score lower than normal on verbal intelligence tests. Problems with relationships, financial woes, and psychological disorders may persist into adulthood (Colman et al., 2009).

When clinicians assess whether conduct disorder might be an appropriate diagnosis for an individual, they will of course talk with the person; however, the nature of conduct disorder is such that a child may not provide complete information about his or her behavior. Thus, clinicians try to obtain additional information from other sources, usually school officials or parents, although even these people may not know the full extent of a child's conduct problems. Usually, the behaviors that characterize conduct disorder are not limited to one setting but occur in a variety of settings: in school, at home, in the neighborhood. This was true for Brad, as described in Case 14.5.

CASE 14.5 ► FROM THE OUTSIDE: Conduct Disorder

Brad was [a teenager and] small for his age but big on fighting. For him, this had gone beyond schoolyard bullying. He had four assault charges during the previous six months, including threatening rape and beating up a much younger boy who was mentally challenged. The family was being asked to leave their apartment complex because of Brad's aggressive behavior and several stealing incidents. Other official arrests included burglaries and trespassing. Brad had participated in a number of outpatient services, including anger management classes in which he had done well, but obviously he was not applying what he had learned to everyday life. He was referred to the [a treatment] program by the juvenile court judge.

Prior to placement, Brad had lived with his mother and older brother. Their family life had been characterized by many disruptions, including contact with several abusive father figures and frequent moves. Mrs. B had epilepsy that was not controlled with medication. She experienced several seizures per week. Brad's older brother also had a record with the juvenile authorities, but his offenses were confined to property crimes and the use of alcohol. He had graduated from an inpatient substance abuse program. Brad and his brother had a history of physical fighting. Prior to the boys' births, Mrs. B had had two children removed from her custody by state protective services. Mrs. B was very protective of Brad. She felt that the police and schools had it "in for him" and regularly defended him as having been provoked or blamed falsely. Although she was devastated at having Brad removed from her home, Mrs. B reported that she could no longer deal with Brad's aggression.

(Chamberlain, 1996, pp. 485–486)

In addition to specifying the intensity of the symptoms, DSM-IV-TR also uses the timing of onset to define two types of conduct disorder, each of which typically has a different course and prognosis:

- *adolescent-onset type*, in which no symptoms were present before age 10; and
- *childhood-onset type*, which is more severe and in which the first symptoms appeared when the child was younger than 10 years old.

Let's examine these two types of the disorder in more detail.

Adolescent-Onset Type

For people with adolescent-onset type, the symptoms of conduct disorder emerge with or after—but not before—puberty. The disruptive behaviors are not likely to be violent and typically include minor theft, public drunkenness, and property offenses, rather than violence against people and robbery, which are more likely with childhood-onset type (Moffitt et al., 2002). The behaviors associated with adolescent-onset type of conduct disorder can be thought of as exaggerations of normal adolescent behaviors (Moffitt & Caspi, 2001). With this type, the disruptive behaviors are usually transient, and adolescents with this disorder are able to maintain relationships with peers (who may behave disruptively along with them). This type of conduct disorder has been found to have a small sex difference; the male to female ratio is 1.5 to 1 (Moffitt & Caspi, 2001).

Childhood-Onset Type

DSM-IV-TR distinguishes only two types of conduct disorder based on the time of onset—adolescence or childhood. But researchers have further identified two variants of childhood-onset conduct disorder, each with different features and pathways to the disorder (Frick & Muñoz, 2006): Some people with childhood-onset type exhibit *callous* and *unemotional* traits (Caputo, Frick, & Brodsky, 1999; Frick, Bodin, & Barry, 2000), which are features of psychopathy (discussed in Chapter 13), and others with childhood-onset type do not possess these traits.

Childhood-Onset Type With Callous and Unemotional Traits

Children and teenagers with callous and unemotional traits are likely to be more aggressive, both when responding to real or perceived provocations and when exhibiting disruptive behavior for some type of gain, such as premeditated theft (Kruh, Frick, & Clements, 2005). This variant of conduct disorder has the highest heritability (Viding et al., 2005). Like adults with psychopathy, these young people seek out exciting and dangerous activities, are relatively insensitive to threat of punishment (Frick et al., 2003), and are strongly oriented toward the possibility of reward (Pardini, Lochman, & Frick, 2003). Moreover, they are less reactive to threatening or distressing stimuli (Frick et al., 2003; Loney et al., 2003).

Researchers propose that the decreased sensitivity to punishment—associated with low levels of fear—underlies the unique constellation of callousness and increased aggression (Frick, 2006; Pardini, Obradovic, & Loeber, 2006). Individuals with this variant of conduct disorder are not concerned about the negative consequences of their violent behaviors. And lacking fear and the bodily arousal that goes along with it, they don't learn to refrain from certain behaviors and thereby fail to internalize social norms or develop a conscience or empathy for others (Frick & Morris, 2004; Pardini, 2006; Pardini, Lochman, & Frick, 2003). In fact, those with conduct disorder with callous and unemotional traits are less likely to recognize emotional expressions of sadness (Blair et al., 2001).

Childhood-Onset Type Without Callous and Unemotional Traits

Some individuals with conduct disorder that arises before puberty do not possess callous or unemotional traits. These people are less likely to be aggressive in general. When they are aggressive, it is usually as a *reaction* to a perceived or real threat; it is not premeditated (Frick et al., 2003). People with this variant of childhood-onset conduct disorder have difficulty regulating their negative emotions: They have high levels of emotional distress (Frick & Morris, 2004; Frick et al., 2003), and they react more strongly to other people's distress (Pardini, Lochman, & Frick, 2003) and to negative emotional stimuli generally (Loney et al., 2003). In addition, they process social cues less accurately, and so are more likely to misperceive such cues and respond aggressively when (mis)perceiving threats (Dodge & Pettit, 2003). Because of their problems in regulating negative emotions, they are more likely to

act aggressively and antisocially in *impulsive* ways when distressed. They often feel bad afterward, but still can't control their behavior (Pardini, Lochman, & Frick, 2003). These people may fall into a negative interaction pattern with parents: When a parent brings up the child's past or present misconduct, the child becomes agitated and then doesn't appropriately process what the parent says, becomes more distressed, and then impulsively behaves in an aggressive manner. The parent may respond with aggression (verbal or physical), creating a vicious cycle (Gauvain & Fagot, 1995).

This variant of conduct disorder is influenced less by genes and more by maladaptive parenting (Oxford, Cavell, & Hughes, 2003); moreover, it is more likely to arise in children with poor verbal reasoning abilities (Loney et al., 1998).

As noted in Table 14.11, the two DSM-IV-TR types of conduct disorder—adolescent- and childhood-onset—differ not only in the timing of onset, but also in other respects.

Table 14.11 ▶ Conduct Disorder Facts at a Glance

Prevalence

- Studies find a wide range of prevalence rates in the general population (1–10%), depending on how the study was conducted and the exact composition of the population studied. About 10% of Americans will be diagnosed with conduct disorder during their lives (Nock et al., 2006).
- Conduct disorder is more likely to occur in urban than in rural areas.
- Conduct disorder is one of the more frequently diagnosed psychological disorders in children.

Onset

- DSM-IV-TR specifies that symptoms of the disorder begin in childhood or adolescence. When symptoms arise before age 10, the diagnosis is childhood-onset type; when there are no symptoms before age 10, it is adolescent-onset type.

Comorbidity

- With the childhood-onset type, common comorbid disorders include oppositional defiant disorder and attention-deficit/hyperactivity disorder (Costello et al., 2003); some studies estimate that up to 90% of children with conduct disorder exhibit symptoms of attention-deficit/hyperactivity disorder (Frick & Muñoz, 2006).
- Among teenagers with conduct disorder, comorbid mood disorders are common (Christophersen & Mortweet, 2001).

Course

- The earlier the onset and the more severe the disruptive behaviors, the worse the prognosis (Barkley et al., 2002; Frick & Loney, 1999).
- Individuals with childhood-onset conduct disorder are likely to develop additional symptoms of the disorder by puberty and continue to have the disorder through adolescence.
- Those with the childhood-onset type are more likely than those with the adolescent-onset type to be diagnosed with antisocial personality disorder in adulthood.

Gender Differences

- During their lives, about 12% of American males and 7% of American females will have had conduct disorder (Nock et al., 2006).
- Although more males than females are diagnosed with this disorder (both types), the sex difference is more marked for the childhood-onset type, with ten males diagnosed for each female (Moffitt & Caspi, 2001).
- Males with conduct disorder tend to be confrontationally aggressive (engaging in fighting, stealing, vandalism, and school-related problems); females tend to be nonconfrontational (lying, truancy, running away, substance use, and prostitution).

What Is Oppositional Defiant Disorder?

The defining features of **oppositional defiant disorder** are overt disobedience, hostility, defiance, and negativity toward people in authority. As noted in Table 14.12, for a diagnosis of oppositional defiant disorder, DSM-IV-TR requires that the individual exhibit four out of eight forms of defiant behavior (Criterion A), many of which are confrontational behaviors, such as arguing with adults, intentionally annoying others, and directly refusing to comply with an adult’s request. Pia did not comply with her parents’ requests to complete her chores or help with other tasks. Her teacher has commented on a similar behavior pattern at school.

Other examples of defiant behaviors include refusing to negotiate, compromise, or adhere to reasonable directions and testing the limits of rules; young children with oppositional defiant disorder may have intense and frequent temper tantrums. (Violent confrontations are not usually part of oppositional defiant disorder.) These behaviors must have been exhibited for at least 6 months, must occur more frequently than would be expected for the individual’s age and developmental level, and must impair functioning.

The disruptive behaviors of oppositional defiant disorder are different in several important ways from those characterizing conduct disorder. Oppositional defiant disorder involves only a subset of the symptoms of conduct disorder—the overtly defiant behaviors—and these are often verbal. The disruptive behaviors of oppositional defiant disorder are

- generally directed toward authority figures;
- not usually violent and do not usually cause severe harm; and
- often exhibited only in specific situations with parents or other adults the individual knows well (Christophersen & Mortweet, 2001).

According to DSM-IV-TR, if an individual meets the diagnostic criteria for both oppositional defiant disorder and conduct disorder, only conduct disorder is diagnosed.

During a clinical interview, the young person may not behave disruptively. In fact, children and adolescents with oppositional defiant disorder often do not feel they are being oppositional, but rather believe that they are responding to unreasonable demands being made of them. It is important for the clinician, then, to obtain information from others when assessing disruptive behaviors. It is also important that the clinician keep in mind any cultural factors that might influence which sorts of behaviors are deemed acceptable or unacceptable. Figure 14.2 illustrates the possible paths for disruptive behavior disorder diagnoses. Table 14.13 lists additional facts about oppositional defiant disorder, and Case 14.6 describes Danny, a 6-year-old with oppositional defiant disorder, whose symptoms are atypical in that he hits his peers.

CASE 14.6 ► FROM THE OUTSIDE: Oppositional Defiant Disorder

Danny is 6 years old and is exhibiting behavior problems in his kindergarten classroom and the child-care after-school program. He is disruptive, hits and touches peers, argues with teachers, becomes easily frustrated, and has temper tantrums when things do not go his way. Danny is considered explosive and unpredictable. He is socially immature and disliked by his peers. Danny’s parents had divorced several years earlier and are both remarried. He lives with his mother but sees his father regularly. The communication between Danny’s parents is strained, and they differ in their opinions on how to handle Danny’s behavior. The parents have different parenting styles and do not always provide Danny with clear and consistent boundaries across the two households.

(August et al., 2007, p. 137)

Table 14.12 ► DSM-IV-TR Diagnostic Criteria for Oppositional Defiant Disorder

A. A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months, during which four (or more) of the following are often present:

- (1) loses temper
- (2) argues with adults
- (3) actively defies or refuses to comply with adults’ requests or rules
- (4) deliberately annoys people
- (5) blames others for his or her mistakes or misbehavior
- (6) is touchy or easily annoyed by others
- (7) is angry and resentful
- (8) is spiteful or vindictive

Note: Consider a criterion met only if the behavior occurs more frequently than is typically observed in individuals of comparable age and developmental level.

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

C. The behaviors do not occur exclusively during the course of a psychotic disorder [Chapter 12] or mood disorder [Chapter 6].

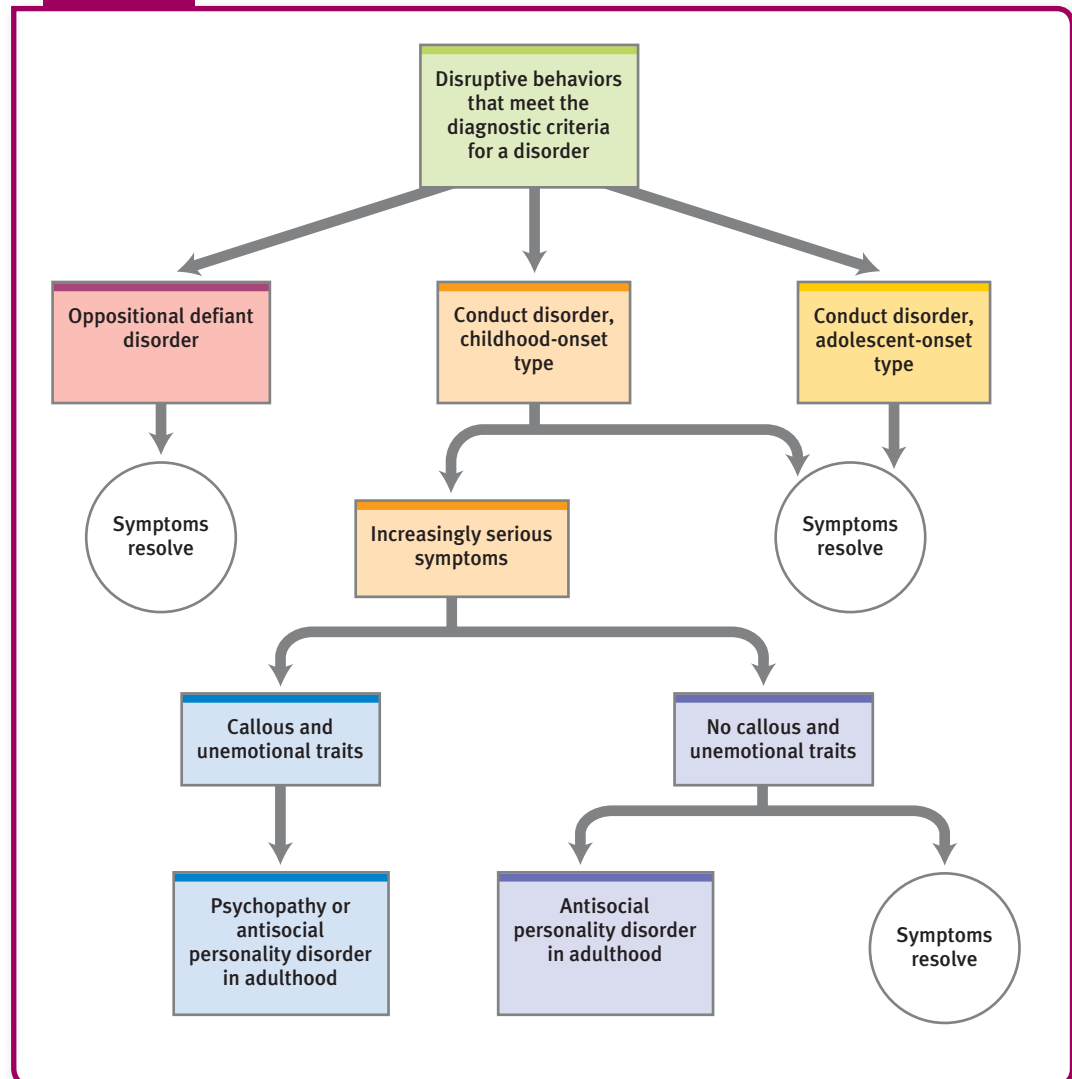

D. Criteria are not met for conduct disorder, and, if the individual is age 18 years or older, criteria are not met for antisocial personality disorder [Chapter 13].

Oppositional defiant disorder

A psychological disorder that typically arises in childhood or adolescence and is characterized by overt disobedience, hostility, defiance, and negativity toward people in authority.

Figure 14.2

14.2 ▸ Typical Paths Related to Disruptive Behavior Disorders Several diagnostic paths are possible for individuals who exhibit significantly disruptive behaviors. Oppositional defiant disorder and conduct disorder can arise either in childhood or in adolescence. Once symptoms reach a level that meets the diagnostic criteria for either disorder, symptoms may (1) remain relatively stable (and hence do not progress to a different part of the diagram), (2) resolve so that the diagnosis no longer applies, or (3) shift, so that a different diagnosis is more appropriate. Although a patient's symptoms can shift from oppositional defiant disorder to conduct disorder, this is not typical. Nevertheless, most research on oppositional defiant disorder has studied the small subset of people who go on to develop conduct disorder.

Oppositional behavior is common among toddlers and adolescents; a clinician must be careful not to make the diagnosis of oppositional defiant disorder unless the disruptive behaviors occur significantly more often or with more intensity than is expected for the individual's age group. Critically, normal oppositional behavior does not impair functioning.

Moreover, symptoms of other disorders may be mistaken for symptoms of oppositional defiant disorder. For instance, a young patient who is psychotic may become angry and defiant, or a depressed individual may become irritable. When disruptive behaviors arise only in the context of a psychotic or mood disorder, oppositional defiant disorder is not the appropriate diagnosis. As another

Table 14.13 ► Oppositional Defiant Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none">Estimates of prevalence rates for this disorder vary widely, from 2% to 16%, depending on the specific population investigated and the specific research methods used.
Onset
<ul style="list-style-type: none">Symptoms usually emerge before 8 years of age, although they may become evident as late as 13.Symptoms are typically observed at home before occurring in other contexts.The onset progresses gradually, over months or even years, until the symptoms reach the point where the diagnostic criteria are met.
Comorbidity
<ul style="list-style-type: none">Attention-deficit/hyperactivity disorder is the most common comorbid disorder (Costello et al., 2003; Lahey, McBurnett, & Loeber, 2000); up to 90% of children with oppositional defiant disorder also exhibit symptoms of attention-deficit/hyperactivity disorder (Frick & Muñoz, 2006).Learning disorders may also co-occur with oppositional defiant disorder.
Course
<ul style="list-style-type: none">Most people with the childhood-onset type of conduct disorder were previously diagnosed with oppositional defiant disorder (Whittinger et al., 2007); however, most people with oppositional defiant disorder do not go on to develop conduct disorder.
Gender Differences
<ul style="list-style-type: none">Before puberty, more males than females are diagnosed with oppositional defiant disorder. After puberty there is no sex difference in prevalence.Males exhibit more persistent and more confrontational symptoms than females do.
Cultural Differences
<ul style="list-style-type: none">Different cultures may have different norms concerning what defiant behaviors are considered inappropriate or unacceptable.
Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

example, people with attention-deficit/hyperactivity disorder may, as a result of their impulsivity or hyperactivity, annoy other people or ignore a request to “calm down” or “sit down.” However, in this context, the behaviors are not expressing defiance but are a result of attention-deficit/hyperactivity disorder.

Sometimes, disruptive behaviors arise as a response to still other disorders or problems, and this possibility should be kept in mind by a clinician. For instance, a child who is having difficulties with schoolwork, perhaps because of dyslexia or another learning disorder, may act up, or be defiant in an effort to hide the problem by distracting the teacher and classmates.

What Is Attention-Deficit/Hyperactivity Disorder?

Individuals who have oppositional defiant disorder or conduct disorder behave disruptively because they want to defy rules, authority figures, or social norms. Those who have a third type of disorder, *attention-deficit/hyperactivity disorder*, often behave disruptively but do so unintentionally. People with attention-deficit/hyperactivity disorder are unusually impulsive and/or are hyperactive, which is why they have difficulty conforming to rules and social norms that call for restraint or calm behavior.

Attention-deficit/hyperactivity disorder (ADHD) is characterized by inattention, hyperactivity, and/or impulsivity. People diagnosed with this disorder vary in which set of symptoms is most dominant; some primarily have difficulty maintaining

Attention-deficit/hyperactivity disorder (ADHD)

A psychological disorder that typically arises in childhood and is characterized by inattention, hyperactivity, and/or impulsivity.

Table 14.14 ▶ DSM-IV-TR Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder

A. Either (1) or (2):

- (1) *inattention*: six (or more) of the following symptoms of inattention have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:
 - (a) often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities;
 - (b) often has difficulty sustaining attention in tasks or play activities;
 - (c) often does not seem to listen when spoken to directly;
 - (d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions);
 - (e) often has difficulty organizing tasks and activities;
 - (f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework);
 - (g) often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools);
 - (h) is often easily distracted by extraneous stimuli;
 - (i) is often forgetful in daily activities.
- (2) *hyperactivity-impulsivity*: six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

Hyperactivity

- (a) often fidgets with hands or feet or squirms in seat;
- (b) often leaves seat in classroom or in other situations in which remaining seated is expected;
- (c) often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness);
- (d) often has difficulty playing or engaging in leisure activities quietly;
- (e) is often “on the go” or often acts as if “driven by a motor”;
- (f) often talks excessively.

Impulsivity

- (g) often blurts out answers before questions have been completed;
- (h) often has difficulty awaiting turn;
- (i) often interrupts or intrudes on others (e.g., butts into conversations or games).

B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before age 7 years.

C. Some impairment from the symptoms is present in two or more settings (e.g., at school [or work] and at home).

D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of a Pervasive Developmental Disorder, Schizophrenia [Chapter 12], or other Psychotic Disorder [Chapter 12] and are not better accounted for by another mental disorder (e.g., Mood Disorder [Chapter 6], Anxiety Disorder [Chapter 7], Dissociative Disorders [Chapter 8], or a Personality Disorder [Chapter 13]).

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

attention, and others primarily have difficulty with hyperactivity and impulsivity. Still others have all three types of symptoms. To meet the criteria for the diagnosis (see Table 14.14), the symptoms must impair functioning in at least two settings, such as at school and at home. The impulsive and hyperactive symptoms are most noticeable and disruptive in a classroom setting. Javier’s difficulty staying in his chair at school, which disrupted the class, may have reflected this disorder. In Case 14.7, an adult recounts how he recognized his own ADHD.

CASE 14.7 ► FROM THE INSIDE: Attention Deficit/Hyperactivity Disorder

Attention-deficit disorder (ADD) was the term used in the third edition of the DSM. In his book *Driven to Distraction: Recognizing and Coping with Attention Deficit Disorder from Childhood Through Adulthood*, psychiatrist Edward Hallowell recounts what happened when he learned about the disorder:

I discovered I had ADD when I was thirty-one years old, near the end of my training in child psychiatry at the Massachusetts Mental Health Center in Boston. As my teacher in neuropsychiatry began to describe ADD in a series of morning lectures during a steamy Boston summer, I had one of the great “Aha!” experiences of my life.

“There are some children,” she said, “who chronically daydream. They are often very bright, but they have trouble attending to any one topic for very long. They are full of energy and have trouble staying put. They can be quite impulsive in saying or doing whatever comes to mind, and they find distractions impossible to resist.”

So there’s a name for what I am! I thought to myself with relief and mounting excitement. There’s a term for it, a diagnosis, an actual condition, when all along I’d thought I was just slightly daft. . . . I wasn’t all the names I’d been called in grade school—“a daydreamer,” “lazy,” “an underachiever,” “a spaceshot”—and I didn’t have some repressed unconscious conflict that made me impatient and action-oriented.

What I had was an inherited neurological syndrome characterized by easy distractibility, low tolerance for frustration or boredom, a greater-than-average tendency to say or do whatever came to mind . . . and a predilection for situations of high intensity. Most of all, I had a name for the overflow of energy I so often felt—the highly charged, psyched-up feeling that infused many of my waking hours in both formative and frustrating ways.

(Hallowell & Ratey, 1994, pp. ix–x)

Because the sets of symptoms vary, clinicians find it useful to classify ADHD into different types. The hyperactive/impulsive type is associated with disruptive behaviors, accidents, and rejection by peers, whereas the inattentive type of ADHD is associated with academic problems that are typical of deficits in executive functions: difficulty remembering a sequence of behaviors, monitoring and shifting the direction of attention, organizing material to be memorized, and inhibiting interference during recall. A third group of patients, with the combined type, has symptoms of each of the other two types.

However, symptoms may change over time; as some children get older, the particular set of symptoms they exhibit can shift, most frequently from hyperactive/impulsive to the combined type (Lahey et al., 2005). Children with ADHD often have little tolerance for frustration, as was true of Edward Hallowell in Case 14.7; such children tend to have temper outbursts, changeable moods, and symptoms of depression. Once properly diagnosed and treated, such symptoms often decrease.

Problems with attention are likely to become more severe when sustained attention is necessary or when a task is thought to be boring, which is what happened to Javier. Various factors (psychological and social) can reduce symptoms, including:

- frequent rewards for appropriate behavior;
- close supervision;
- being in a new situation or setting;
- doing something interesting; and
- having someone else’s undivided attention.

In contrast, symptoms are likely to become more severe in group settings, where the individual receives less attention or rewards.

Socially, people with ADHD may initiate frequent shifts in the topic of a conversation, either because they are not paying consistent attention to the conversation or they are not following implicit social rules: Those with symptoms of hyperactivity may talk so much that others can’t get a word in edgewise, or they may inappropriately start conversations. These symptoms can make peer relationships difficult.

Figure 14.3

14.3 ► Reduction in ADHD Symptoms From Childhood to Adulthood By adulthood, the symptoms of (a) hyperactivity and (b) impulsivity diminish more in people with ADHD than do the symptoms of (c) inattention (Biederman, Mick, & Faraone, 2000). In *syndromic remission*, symptoms improve and no longer meet diagnostic criteria; in *symptomatic remission*, symptoms improve but diagnostic criteria are still met (Biederman et al., 2000).

In addition, symptoms of impulsivity can lead to increased risk of harm. As shown in Figure 14.3, as the child heads into adulthood, hyperactive and impulsive symptoms tend to decrease but not disappear. Symptoms of inattention, however, do not tend to decrease as much (Biederman, Mick, & Faraone, 2000). Additional facts about ADHD are presented in Table 14.15.

Distinguishing Between Attention-Deficit/Hyperactivity Disorder and Other Disorders

Some symptoms of ADHD overlap with those of other disorders. For instance, the hyperactive and impulsive symptoms of ADHD may appear similar to those of hypomania or mania (bipolar disorder, Chapter 6) or to anxiety symptoms (such as those that may arise with anxiety disorders, Chapter 7). In addition, symptoms of inattention may overlap with some of the symptoms of dissociative disorders (Chapter 8). Moreover, symptoms of substance-related disorders (Chapter 9) and personality disorders (Chapter 13) may overlap with both inattention and hyperactive/impulsive symptoms.

However, two factors distinguish ADHD from the other disorders: (1) childhood onset, and (2) the relatively large number of symptoms of inattention and/or hyperactivity/impulsivity necessary for the diagnosis. But even these two factors may not allow a clinician to distinguish disruptive behaviors that arise from hyperactivity or impulsivity from disruptive behaviors that arise from defiance associated with oppositional defiant disorder or conduct disorder. The extremely high comorbidity between ADHD and oppositional defiant disorder or conduct disorder requires clinicians to assess carefully the reason for a child's persistent disruptive behavior. A general rule of thumb is that individuals with ADHD and *not* oppositional defiant disorder or conduct disorder do not intentionally violate the rights of others. For instance, Javier didn't hurt others physically, nor had his parents or teachers noticed any significant lying or stealing. Moreover, his disruptive behaviors in the classroom did not seem willful; rather, it seemed as though he couldn't help himself when he jumped out of his seat. And when he stood 5 inches from his classmates' faces while talking to them, he seemed happy and excited, not threatening. However, many children are diagnosed with both conduct disorder and ADHD, indicating that they intentionally violate rules *and* are also impulsive and hyperactive or have problems with attention.

Table 14.15 ▶ Attention-Deficit/Hyperactivity Disorder Facts at a Glance**Prevalence**

- The estimated prevalence of ADHD in school-aged children increased from 6% in 1997 to 9% in 2006 (National Center for Health Statistics, 2008).
- Prevalence among American adults is about 4% (Kessler et al., 2006).

Comorbidity

- Common comorbid disorders include mood and anxiety disorders and learning disorders.
- Children with hyperactive and impulsive symptoms are more likely to be diagnosed with oppositional defiant disorder or conduct disorder than are those with inattentive symptoms (Christophersen & Mortweet, 2001): In surveys of the general population, 50–75% of children with ADHD also meet the criteria for conduct disorder (Kazdin, 1995). Another study found that over half of children with ADHD had comorbid oppositional defiant disorder (Biederman et al., 1996).

Onset

- Children are not usually diagnosed before age 4 or 5 because the range of normal behavior for preschoolers is very wide.
- In younger children, the diagnosis is generally based more on hyperactive and impulsive symptoms than on inattention symptoms.
- DSM-IV-TR requires that the disorder have its onset by age 7; however, research suggests that onset may occur up to age 12. Note, however, that diagnosis may occur much later.

Course

- Symptoms of ADHD become obvious during the elementary school years, when attentional problems interfere with schoolwork.
- By early adolescence, the more noticeable signs of hyperactivity—difficulty sitting still, for example—typically diminish to a sense of restlessness or a tendency to fidget.
- Children who had ADHD but not oppositional defiant disorder or conduct disorder in childhood have a higher risk of developing adolescent-onset conduct disorder than do peers who had none of those disorders in childhood (Mannuzza et al., 2004).
- As adults, people with ADHD may avoid sedentary jobs because of their restlessness.

Gender Differences

- Males are more likely—in one survey, more than twice as likely—to be diagnosed with ADHD, particularly the hyperactive/impulsive type, although this gender difference may reflect a bias in referrals to mental health clinicians rather than any actual difference in prevalence (Biederman et al., 2005; National Center for Health Statistics, 2008).

Cultural Differences

- In the United States, non-Hispanic white children are more likely to be diagnosed with ADHD than are Hispanic or black children (Havey et al., 2005; Stevens, Harman, & Kelleher, 2005).
- Worldwide, the prevalence of the disorder among children averages about 5% (Polanczyk & Rohde, 2007), although some studies find higher prevalence rates (Bird, 2002; Ofove, Ofove, & Meyer, 2006); the variability across countries can be explained by the different thresholds at which behaviors are judged as reaching a symptomatic level, as well as somewhat different diagnostic criteria (Bird, 2002).

Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

Criticisms of the DSM-IV-TR Diagnostic Criteria

Clinicians and researchers have pointed out numerous problems with the DSM-IV-TR criteria for ADHD. First, the diagnostic criteria for children do not necessarily apply very well to adults; adults with less than five symptoms can be clearly impaired, even though they don't exhibit the minimum number (six) of symptoms required for a diagnosis (McGough & McCracken, 2006). Second, according to the DSM criteria, if symptoms don't arise until after age 7, the diagnosis of ADHD is not, strictly speaking, applicable (American Psychiatric Association, 2000). However, research studies

that examined people whose symptoms arose after age 7 (but generally by age 12) found that the symptoms were virtually identical to those of people with an earlier onset of the disorder, which suggests that the age cutoff is not meaningful (Faraone et al., 2006; McGough & Barkley, 2004).

Third, symptoms of hyperactivity may be different in females than in males: Girls who have hyperactive symptoms may talk more than other girls or may be more emotionally reactive, rather than hyperactive with their bodies (Quinn, 2005). Some researchers propose that ADHD is underdiagnosed in girls, who are less likely to have behavioral problems at school and so are less likely to be referred for evaluation (Quinn, 2005). In fact, female teenagers with ADHD are likely to be diagnosed with and treated for depression before the ADHD is diagnosed (Harris International, 2002, cited in Quinn, 2005).

Teachers are often the ones who first raise the possibility that a particular child has ADHD, and they are more likely to refer for evaluation children who disrupt the class (hyperactive/impulsive type). One study found that teachers were more likely to identify students as having ADHD when their class size was larger, and non-Hispanic white children were more likely to be identified than were Hispanic children (Havey et al., 2005). Other studies find that white children are more often diagnosed—and treated—than black children (Stevens, Harman, & Kelleher, 2005).

Before diagnosing ADHD, however, a mental health clinician should be sure that any difficulties in finishing tasks are a result of attentional problems, and not an oppositional attitude or difficulty in understanding the instructions. For instance, it turns out that Pia Enriquez simply hadn't been paying attention when her parents reminded her of her chores or asked her to set the table. Pia's "absent-minded professor" demeanor masked that fact that she has difficulty paying attention and becomes bored easily (particularly in the classroom, where she quickly grasps the underlying concepts in the material the teacher presents). When diagnosing adults with ADHD, clinicians should seek corroboration from school records or family members.

Understanding Disorders of Disruptive Behavior and Attention

Given the high comorbidity and symptom overlap among the three disorders—conduct disorder, oppositional defiant disorder, and ADHD—we'll focus on the disorder that is best understood, ADHD. Studies of factors related to oppositional defiant disorder and conduct disorder probably include participants who also have ADHD, which makes it difficult to determine which factors are uniquely associated with oppositional defiant disorder and conduct disorder and *not* ADHD.

Neurological Factors

Research on ADHD has revealed that people who have this disorder have abnormal brain structure and function, and also has begun to characterize the role that neurotransmitters and genes have in these brain abnormalities. Unfortunately, researchers are only beginning to consider the different possible types of the disorder separately—and thus at present only a very coarse picture is beginning to emerge.

ADHD and Brain Systems

As noted earlier, people with ADHD may have impaired executive function (Kiliç et al., 2007; Stuss et al., 1994). In addition, children and adults with ADHD cannot estimate time accurately, which affects their ability to plan and follow through on commitments (Barkley et al., 2001; Kerns, McInerney, & Wilde, 2001; McInerney & Kerns, 2003; Riccio et al., 2005). Such functions rely in part on the frontal lobes.

In fact, researchers have proposed that the behavioral problems that characterize people with ADHD may arise, at least in part, from impaired frontal lobe functioning. Two sorts of findings that support this view focus on brain structure and on brain function. Regarding brain structure, children and adolescents with this

disorder have smaller brains than do children and adolescents without the disorder, and the deficit in size is particularly marked in the frontal lobes (Schneider, Retz et al., 2006; Sowell et al., 2003; Valera et al., 2007). Indeed, particular parts of the frontal lobes have been shown to be smaller in adults with ADHD (Durstun et al., 2004; Hesslinger et al., 2002). However, the anatomical abnormalities are not restricted to the frontal lobes. Parts of the temporal lobes are smaller than normal in children and adolescents who have the disorder (Sowell et al., 2003), as are portions of the corpus callosum, the basal ganglia, and the cerebellum (Castellanos et al., 2002; Schrimsher et al., 2002; Valera et al., 2007). The cerebellar deficit is particularly interesting because this brain structure is crucial to attention and timing; in fact, the smaller this structure, the worse the symptoms of ADHD are (Castellanos et al., 2002; Mackie et al., 2007).

Some of the brain differences between people who have ADHD and those who do not may actually arise because the brain has attempted to compensate for the impaired regions. Perhaps critically, at least some of the differences found in the brains of children—notably those in the basal ganglia—do not persist into adulthood (Castellanos et al., 2002; Schneider et al., 2006). This finding is consistent with the fact that over half of the children who are diagnosed with ADHD do not meet the diagnostic criteria when they become adults (Schneider et al., 2006).

Regarding brain function, the research results indicate that ADHD is not a result of impaired functioning in any single brain area, but rather emerges from how different areas interact. As the anatomical abnormalities would suggest, neuroimaging studies have revealed many patterns of abnormal brain functioning in people who have ADHD (Rubia et al., 2007; Stevens, Pearlson, & Kiehl, 2007; Vance et al., 2007). In general, neural structures involved in attention, including portions of the frontal and parietal lobes, tend not to be activated as strongly (during relevant tasks) in people with this disorder as in people without it (e.g., Stevens, Pearlson, & Kiehl, 2007; Schneider et al., 2006; Vance et al., 2007). However, virtually every lobe in the brains of individuals with ADHD has been shown not to function normally during tasks that draw on their functions (e.g., Mulas et al., 2006; Schneider et al., 2006; Vance et al., 2007).

In addition, abnormal brain functioning can influence the autonomic nervous system (see Chapter 2): ADHD (and some types of conduct disorder) has been associated with unusually low arousal in response to normal levels of stimulation (Crowell et al., 2006), a response that could explain some of the stimulation-seeking behavior seen in individuals with this disorder. That is, these people could engage in stimulation-seeking behavior in order to obtain an optimal level of arousal.

ADHD and Neural Communication

The overall pattern of difficulties that characterizes ADHD suggests problems with multiple neurotransmitters that are involved in coordinating and organizing cognition and behavior. For one, dopamine apparently does not function effectively in the brains of people with this disorder (Volkow et al., 2007). This malfunction may arise for any of various reasons, including too few of the relevant receptors or problems in removing dopamine from the synapse (Swanson et al., 2007). But dopamine functioning is not the only issue: Imbalances in serotonin and norepinephrine may also contribute to the disorder (Arnsten, 2006; Gainetdinov et al., 1999; Waldman & Gizer, 2006), and the activity of other neurotransmitters may also be disrupted (Pattij & Vanderschuren, 2008). Given the number of brain areas that are involved, it is not surprising that problems with multiple neurotransmitters are likely to be associated with the disorder.

ADHD and Genetics

Genes may be one reason why people with ADHD have abnormal brain systems and disrupted neural communication. Indeed, not only does this disorder run in families, but also parent and teacher reports indicate that it is highly correlated among monozygotic twins (with correlations ranging from 0.60 to 0.90). In addition, a large set of data reveals that this disorder is among the most heritable of psychological disorders (Martin et al., 2006; Stevenson et al., 2005; Waldman & Gizer, 2006).

However, as with most psychological disorders that are influenced by genes, a combination of genes—not a single gene—probably contributes to it (Faraone et al., 2005). In fact, over a dozen different genes have so far been identified as possibly contributing to this disorder (Guan et al., in press; Swanson et al., 2007; Waldman & Gizer, 2006). Many of these genes have been shown to affect the activity of the neurotransmitters that likely are involved in the disorder. In addition, some of these genes may also contribute to conduct disorder and oppositional defiant disorder, which would, at least in part, account for the high comorbidity among these disorders (Dick et al., 2005; Jain et al., 2007).

Genetic factors do not occur in a vacuum. In fact, such factors often interact with environmental events, which lead a given individual to be more or less sensitive to teratogens prenatally or to environmental exposure during early childhood (Jacobson et al., 2006; Kahn et al. 2003; Pineda et al., 2007; Swanson et al., 2007). Researchers have identified several environmental risk factors. For example, children whose mothers smoked while pregnant are much more likely to develop ADHD than are children whose mothers did not smoke (Braun et al., 2006), and this relationship appears to be particularly strong for children who have a specific gene (Neuman et al., 2007).

Neurological Factors in Conduct and Oppositional Defiant Disorders

Finally, although ADHD is by far the best-understood of the disruptive disorders, researchers have begun to investigate the other two. Much of what is known about neurological factors related to oppositional defiant disorder and conduct disorder overlaps with what is known about antisocial personality disorder (see Figure 13.6). This is not surprising, given the fact that most people with antisocial personality disorder or psychopathy had oppositional defiant disorder and/or conduct disorder during childhood or adolescence. Moreover, many, if not most, of the participants in those studies probably also had comorbid ADHD (although most people with ADHD don't develop oppositional defiant disorder, conduct disorder, or antisocial personality disorder). It is clear that genes play a role (Gelhorn et al., 2006; Hudziak et al., 2005; Maes et al., 2007): Both oppositional defiant disorder and conduct disorder are more common among children whose biological parents were criminals or had been diagnosed with oppositional defiant disorder, conduct disorder, ADHD, antisocial personality disorder, a substance use disorder, or a mood disorder (Frick & Muñoz, 2006; Haber, Jacobs, & Heath, 2005). All of these disorders except depression are considered to reflect externalizing problems, related to undercontrol (see Chapter 3).

Conduct disorder with callous and unemotional traits is accompanied by decreased sensitivity to—and arousal by—punishment, which is associated with a temperament referred to as low harm avoidance (Frick et al., 2003). This temperament in turn impedes the ability to internalize appropriate social norms and develop a conscience (Pardini, 2006). Moreover, individuals with this type of conduct disorder are likely to be high in another aspect of temperament, reward dependence; they are strongly motivated by the possibility of reward. But at the same time they are also low in persistence; they have a low tolerance for frustration (Gray, 1987; Zuckerman, 1991).

Psychological Factors: Recognizing Facial Expressions, Keeping Track of Time

We'll first examine the psychological factors of the best understood of the disorders that involve disruptive behavior—ADHD. In addition to problems with attention and executive function, people with ADHD may have other, perhaps less obvious, difficulties. As with autism, one problem is recognizing emotions in facial expressions—not all emotions, but anger and sadness in particular. Why? The answer isn't known, but one suggestion is that these people might have had very negative experiences with others who are sad or angry, and these unpleasant experiences motivate them to tune out such expressions (Pelc et al., 2006).

In addition, children with ADHD appear to have an attributional style that leaves them vulnerable to low self-esteem. In one study (Milich, 1994), children with ADHD initially overestimated their ability to succeed in a challenging task, and—when confronted with failure—boys with ADHD became more frustrated and were less likely to persist with the challenging task than were boys in a control group. Moreover, in another study (Collett & Gimpel, 2004), children with ADHD attributed the cause of negative events to global and stable characteristics about themselves (“I am a failure”) rather than external, situational factors (“That was a very challenging task”). Conversely, children with ADHD were more likely than children without a psychological disorder to attribute positive events to external, situational causes. These attribution patterns were observed regardless of whether children were taking medication for ADHD. And such patterns are often seen in people who experience low self-esteem (Sweeney, Anderson, & Bailey, 1986; Tennen & Herzberger, 1987).

Low self-esteem among those with ADHD isn’t restricted to children. One study compared college students with and without ADHD and matched them to control participants who had comparable demographic variables and grade-point averages; students with ADHD reported lower self-esteem and social skills than did students without ADHD (Shaw-Zirt et al., 2005). Other studies report lower self-esteem among adolescents with ADHD (Slomkowski, Klein, & Mannuzza, 1995).

Furthermore, problems with self-esteem are not limited to people with ADHD but are also present in those who have other disorders of disruptive behavior. However, people with oppositional defiant disorder and conduct disorder often fall at the ends of a self-esteem continuum: They either have low self-esteem or they have overly inflated self-esteem—believing themselves to be superior in ways that are not corroborated by their characteristics or behavior.

Social Factors: Blame and Credit

The self-esteem of children with ADHD may also be related to their parents’ attributions: Although parents don’t necessarily blame their children for ADHD-related behaviors, they don’t give their children as much credit for positive behaviors as do parents of children without ADHD (Johnston & Freeman, 1997). The parents of children with ADHD tend to attribute children’s positive behaviors to random situational factors.

Parents of children with ADHD may also feel frustrated and pessimistic about their children’s abilities and behavior. In a study aimed at exploring these emotions, researchers compared the feelings of parents of children (aged 7 to 12) with and without ADHD while each child-parent pair was engaged in either “getting ready” activities (such as getting ready to leave the house to go to school) or “other” activities (Whalen et. al. 2006). Each parent carried around a personal digital assistant (PDA) that beeped at unpredictable times. At the sound of the beep, parents filled in an electronic diary that asked about the current activity and parents’ feelings. Parents of children with ADHD reported spending more time on “getting ready” activities. They also reported more feelings of anger and stress, were less likely to be in a good mood, and had more arguments with their children during such activities than did parents of children without ADHD. Although the researchers did not observe the actual behaviors of the parents, it is reasonable to surmise that any parent who reported negative feelings may have acted toward his or her child in ways that reflected these feelings—either overtly and explicitly, or by being irritable or impatient.

For people diagnosed with oppositional defiant disorder or conduct disorder, all of the social factors associated with ADHD play a role, as do many of the factors that give rise to antisocial personality disorder: harsh or inconsistent punishment and a family history of substance abuse or antisocial personality disorder. In fact, studies have demonstrated that psychological and social factors play a larger role in oppositional defiant disorder and conduct disorder than in ADHD (Frick & Muñoz, 2006). However, genetic factors can also account for part of the effect of these social

JupiterImages/Brand X/Alamy

People with ADHD can have difficulty picking up on certain social cues—specifically, they may not recognize the facial expressions that correspond to anger and sadness.

factors: Parents who develop substance use disorders or antisocial personality disorder may have temperaments (influenced by genes) that increase the likelihood that these disorders will emerge; however, such parents may also pass the genes to their children, making it difficult to distinguish among the different influences.

Other social factors related to oppositional defiant disorder and conduct disorder—with or without comorbid ADHD—are intertwined with psychological factors (Levy & Orlans, 1999, 2000; Ogloff, 2006). Children exposed to neglect or violence—in the neighborhood, among peers, or at home—observe others showing a disregard for social norms; through observational learning, they may come to imitate those behaviors (psychological factor). Parental neglect or inconsistent parenting is also associated with a child's disruptive behavior: Children may receive positive attention or praise rarely and negative attention more frequently—when breaking rules or being disruptive. They then learn to obtain attention by acting up. Moreover, parents may be inconsistent in setting limits on inappropriate behavior, and so children learn that nothing bad usually happens if they break rules (and if parents do intervene, the children receive attention!) (Dodge & Pettit, 2003; Loeber & Farrington, 2000; Moffitt, 2003; Raine, 2002). Thus, as we saw with antisocial personality disorder and psychopathy, genes may predispose someone toward certain types of behavior, but the environment in which a child is raised and how the child is treated influence whether such behavior is exhibited (Caspi et al., 2002; Mednick, Gabriella, & Hutchings, 1984).

Finally, social factors can indirectly influence the development of these disorders. For example, children typically are raised in homes selected by their parents—based on various social factors such as parents' financial status, proximity to extended family, and community resources. If children are raised in a house where lead paint has been applied, they may be more vulnerable to ADHD. In fact, children whose hair contains higher levels of lead (which is a measure of exposure to lead, perhaps from lead paint in one's home environment) are more likely to have ADHD than are children who have lower levels of lead in their hair (Tuthill, 1996). Even children who were exposed to very low levels of lead in their environment are more likely to develop ADHD than are children who were not exposed (Nigg, 2006).

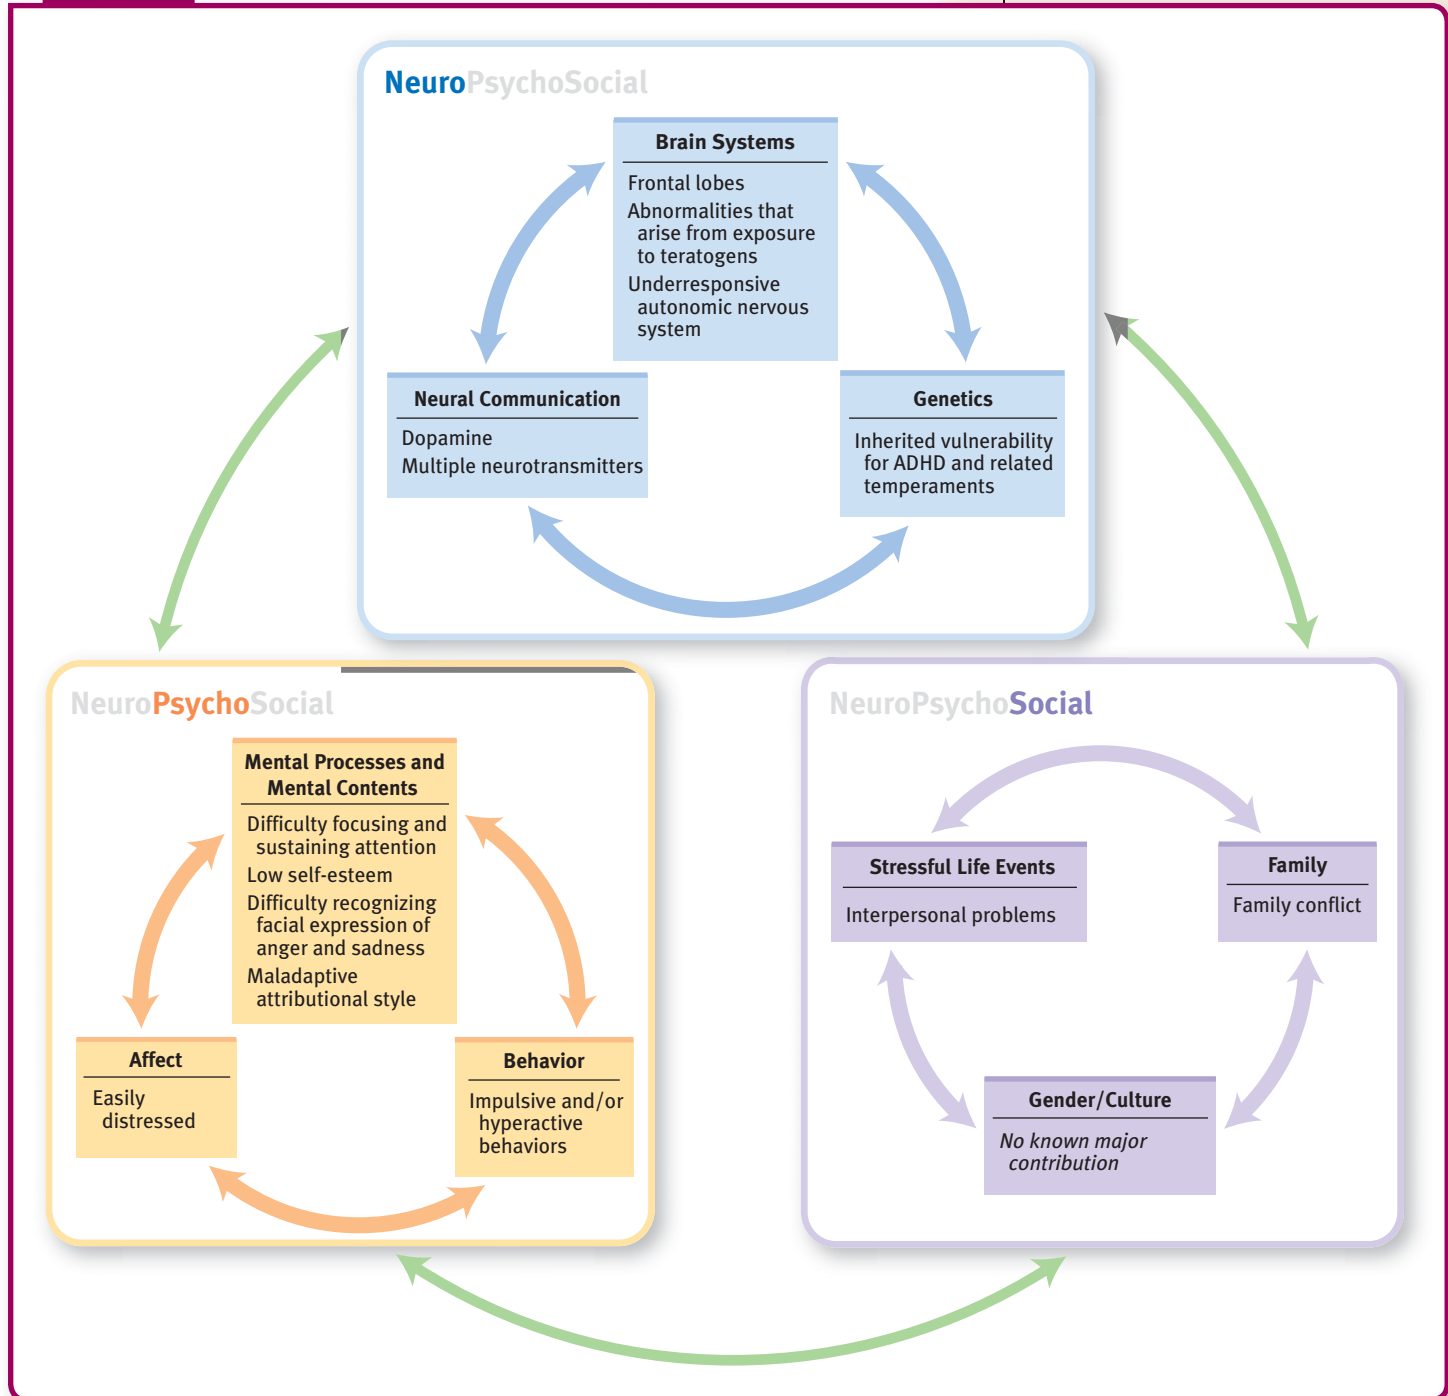

FEEDBACK LOOPS IN ACTION:

Attention-Deficit/Hyperactivity Disorder

In this section, we examine how the different factors related to attention-deficit/hyperactivity disorder create feedback loops (see Figure 14.4). Current research suggests that psychological and social factors contribute to the development of ADHD in those who are neurologically vulnerable to the disorder because of genetics, prenatal factors (such as the mother's smoking), or environmental factors (such as exposure to lead in early childhood; Laucht et al., 2007).

Consider the finding that children with ADHD are less accurate at recognizing sad and angry facial expressions (Pelc et al., 2006). Such deficits, particularly difficulty in recognizing anger, are associated with more interpersonal problems. These results suggest that when peers or adults (typically parents or teachers) show—rather than tell—their displeasure about the behavior of a child who has ADHD, that child is less likely to perceive (psychological factor) the social cue (social factor) than is a child who does not have the disorder. The inability to perceive others' displeasure in turn creates additional tension for both the child and those who interact with him or her. In fact, children with ADHD are more likely than those without the disorder to be rejected by their peers (Mrug et al., 2009). Moreover, other people's responses to the child's behavior (social factor) in turn influence how the child comes to feel about himself or herself (psychological factor; Brook & Boaz, 2005).

Other research results suggest that the family environment is associated with ADHD. In particular, family conflict is higher in families that include a child

Figure 14.4**14.4 ► Feedback Loops in Action: Attention-Deficit/Hyperactivity Disorder**

with ADHD than in control families (Pressman et al., 2006). However, do family environments that are higher in conflict *contribute* to ADHD in those who are vulnerable? Or do the symptoms of the disorder—inattention, hyperactivity, or impulsivity—create more tension in the family? Or do difficulties associated with the disorder, such as difficulty in recognizing angry or sad facial expressions, increase family tension? It may be that all these possible influences occur.

Treating Disorders of Disruptive Behavior and Attention

Treatments for disorders of disruptive behavior and attention are usually comprehensive, targeting more than one type of factor and possibly all three factors. And children with ADHD may be legally entitled to special services and accommodations in school. Specific treatments for ADHD focus on both attentional symptoms and, when present, hyperactivity/impulsivity symptoms.

Targeting Neurological Factors: Medication

Although there are no medications specifically intended for oppositional defiant disorder or conduct disorder, medication for ADHD often helps children with comorbid oppositional defiant disorder or conduct disorder. One type of medication for ADHD targets dopamine, which—as noted earlier—plays a key role in the functioning of the frontal lobe (Solanto, 2002). Many of these medications are stimulants, which may sound counterintuitive because people with ADHD don't seem to need more stimulation. However, these stimulants increase attention and reduce general activity level and impulsive behavior. The medications appear to disrupt the reuptake of dopamine, leaving more dopamine in the synapse and thus correcting at least some of the imbalance in this neurotransmitter that has been observed in the brains of people with ADHD (Volkow et al., 2005). In addition, this disorder may arise in part because the person is understimulated, and hence seeks additional stimulation; by providing stimulation internally, the medications reduce the need to seek it externally. Consistent with this view, researchers have found that people with ADHD perform memory and verbal tasks better when auditory white noise is present in the background (which presumably stimulates them) than when such noise is not present; in contrast, the presence of white noise impairs performance for control participants (Söderlund, Sikström, & Smart, 2007).

Stimulant medications for ADHD may contain *methylphenidate* (Ritalin, Concerta, and Focalin) or an amphetamine (such as Adderall), and are available in shorter-lasting formulas (requiring two or three daily doses) and in a timed-release formula (requiring only one dose per day). Methylphenidate is also available as a daily skin patch. For some people, side effects of these medications can include headache, insomnia, and decreased appetite, and the medications may be associated with increased risk of heart problems. About 65–75% of people with ADHD who receive stimulants improve (compared to 4–30% of controls who receive placebos), and the side effects are not severe for most people (Pliszka, 2007; Pliszka et al., 2006). In fact, stimulants have been shown to improve the functioning of various brain areas that are impaired in this disorder (Bush et al., 2008; Clarke et al., 2007; Epstein et al., 2007). The Federal Drug Administration has approved these medications for children 6 years old and over; for children under 6, the medications appear to be less effective than they are for older children, and side effects, such as slowed growth and weight loss, are worse (Wigal et al., 2006).

Another medication for ADHD is *atomoxetine* (Strattera); it is a noradrenaline reuptake inhibitor, not a stimulant. Atomoxetine has effects and side effects similar to those of the stimulant medications (Kratochvil et al., 2002) and currently is the medication of choice for people with both ADHD and substance abuse.

Medications for ADHD reduce impulsive behaviors, which seems to decrease related aggressive behaviors (Frick & Morris, 2004). This effect can have wide-ranging consequences. In particular, as noted earlier, for some children, the symptoms of ADHD give rise to feedback loops involving interactions with their families or with peers that cause the disruptive behaviors to escalate. Successful treatment with medication disrupts these feedback loops, reducing the frequency and intensity of disruptive behaviors, which in turn leads family members or peers not to become as irritated and angry, which thereby reduces their

undercutting the child's self-esteem (Frick & Muñoz, 2006; Hinshaw et al., 1993; Jensen et al., 2001).

Targeting Psychological Factors: Treating Disruptive Behavior

Treatments that target psychological factors have been developed for oppositional defiant disorder, conduct disorder, and ADHD. These treatments usually employ behavioral and cognitive methods to address disruptive behaviors. One reason for such behaviors is that children with any of these disorders tend to have low frustration tolerance and difficulty in working for delayed—rather than immediate—reward. Thus, behavioral methods may focus on helping such children restrain their behavior and accept a delayed reward. Specific techniques include a reinforcement program that uses concrete rewards, such as a toy, and social rewards, such as praise or special time with a parent. These methods slowly increase the delay until the child receives either a concrete reward (“Now you can have that toy”) or a social reward (“You did a great job, I’m proud of you”), which should motivate the child to control behavior for a delayed reward in the future (Sonuga-Barke, 2006).

Behavioral methods for treating all three disorders may also be used to modify social behaviors, such as not responding to others aggressively or not interrupting others. For example, when children enter preschool or kindergarten, it may be the first time they have to sit quietly for a length of time and wait for a turn to participate. Often the teacher will ask children to raise a hand and wait until called on to answer a question. A child with ADHD will be more likely than other children to speak out of turn or to keep vigorously waving a raised hand, trying to get the teacher's attention. A program of rewarding the child for increasingly longer times of not speaking out or waving frantically can teach the child to behave with more restraint, which can ease relations with classmates.

Cognitive methods seek to enhance children's social problem-solving abilities. Specifically, the therapist helps the child interpret social cues in a more realistic way—for instance, acknowledging that the other person may not have hostile motives when he asked you to move your backpack—and develop more appropriate social goals and responses (Dodge & Pettit, 2003). Through skills-building, modeling, and role-playing, the treatment also shows the child how to inhibit angry or impulsive reactions and to learn more effective ways to respond to others. The therapist praises the child's successes in these areas. To enhance the generalizability of the new skills to life outside the therapy session, parents and teachers may be asked to help with role-playing and modeling and to use praise in their contacts with the child.

When a child's symptoms interfere with functioning in school, an IEP may specify classroom accommodations, such as increased time to complete tests and more frequent but shorter breaks throughout the day.

Targeting Social Factors: Reinforcement in Relationships

Most of the treatments that target social factors are designed to help parents—and teachers when necessary—to make more systematic and consistent use of operant conditioning principles: reinforcement, punishment, and extinction. Through operant conditioning, such treatment is designed to shape a child's prosocial behavior and decrease defiant or impulsive behavior. In addition, group therapy and various other techniques may be used to improve social skills.

Contingency Management: Changing Parents' Behavior

Contingency management is a procedure for modifying behavior by changing the conditions that lead to, or are produced by, it. Treatment may target parents of children with ADHD, to help them set up a contingency management program with their child—particularly in cases in which the parents have been inconsistent in their use of praise and other reinforcers as well as punishment (Frick & Muñoz, 2006).

Contingency management

A procedure for modifying behavior by changing the conditions that led to, or are produced by, it.

The first step of contingency management training with parents is psychoeducation—teaching the parents that the symptoms are not the result of intentional misbehavior but part of a disorder (Barkley, 1997, 2000). The training then is intended to:

1. change parents' beliefs about the reasons for their child's behavior so that parents approach their child differently and develop realistic goals for their child's behavior;
2. help parents to institute behavior modification, which includes paying attention to desired behaviors, being consistent and clear about directions, and developing reward programs; and
3. teach parents to respond consistently to misbehavior.

Parent training, then, targets social factors—interactions between parents and child. Changes in the way parents think about and interact with their child, in turn, change the child's ability to control behavior (psychological factor). Parent training may be the best treatment for families who have children with mild ADHD or preschoolers with ADHD (Kratochvil et al., 2004).

Parent Management Training

Parent management training is designed to combine contingency management techniques with additional techniques that focus on improving parent-child interactions generally—improving communication and facilitating real warmth and positive interest in the parent for his or her child (Kazdin, 1995).

Multisystemic Therapy

Multisystemic therapy (Henggeler et al., 1998) is based on family systems therapy and focuses on the context in which the child's behavior occurs: with peers, in school, in the neighborhood, and in the family. This comprehensive treatment may involve family and couples therapy, interventions with peers, CBT with the child, and an intervention in the school (such as meeting with the child's teacher or directly assisting in the classroom to help the child manage his or her behavior). The specific techniques employed are tailored to the systems in the child's life that need to be changed.

A substantial minority of children with conduct disorder and oppositional defiant disorder don't respond to a given treatment or, if they do, their disruptive behaviors may decrease only to the point where the diagnostic criteria for a disruptive behavior disorder are no longer met; usually, though, the disruptive behaviors do not decrease to normal levels (Kazdin, 1995). Moreover, success in changing a child's behavior in one setting—at home, for example—does not necessarily generalize to other settings, such as the classroom. Younger children who have relatively minor symptoms are most likely to benefit from the treatments that target social factors.

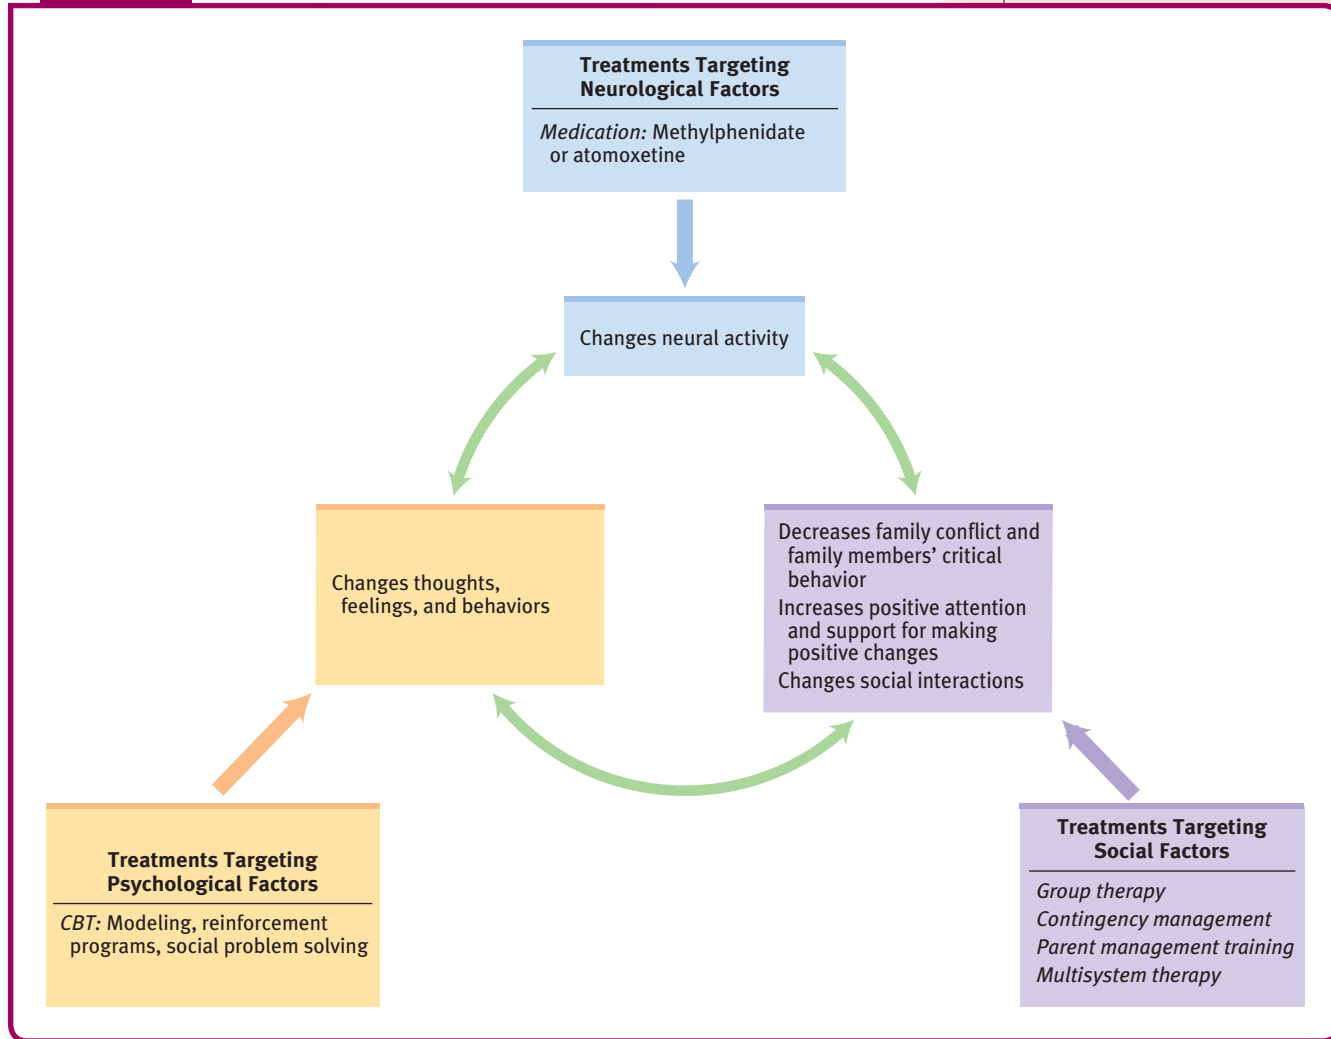

FEEDBACK LOOPS IN TREATMENT: Treating Attention-Deficit/Hyperactivity Disorder

Let's take a closer look at treatment for ADHD, examining the feedback loops among the various factors (see Figure 14.5).

At first glance, medication might seem to have its effects solely through neurological mechanisms, but this isn't so. Taking medication (neurological factor) not only leads to increased control of attention and hyperactive or impulsive behaviors, but it is also associated with higher levels of self-esteem (psychological factor; Frankel et al., 1999) and improved social functioning (social factor; Chacko et al., 2005). And better social functioning feeds back to improve self-esteem, which can lead a child not to seek attention as vigorously.

Other feedback loops originate from programs for parents or the family (which target social factors); such interventions in turn create feedback loops with psychological factors—improving the child's thoughts, feelings, and behaviors.

Figure 14.5**14.5 ► Feedback Loops in Treatment: Attention-Deficit/Hyperactivity Disorder****Key Concepts and Facts About Disorders of Disruptive Behavior and Attention**

- Conduct disorder is characterized by a violation of the basic rights of others or of societal norms that are appropriate to the individual's age. Conduct disorder involves four types of behavior: aggression to people and animals, destruction of property, deceitfulness or theft, and serious violation of rules. Symptoms may be mild, moderate, or severe, and the disorder may begin in childhood or adolescence. Conduct disorder is commonly comorbid with attention-deficit/hyperactivity disorder and substance use or abuse.
- Childhood-onset conduct disorder with callous and unemotional traits has the highest heritability among the various types of conduct disorder; this variant is also associated with more severe symptoms. Individuals with childhood-onset

conduct disorder *without* callous and unemotional traits are less aggressive, although they are likely to be aggressive impulsively, in response to (mis)perceived threats. Adolescent-onset conduct disorder tends to involve mild symptoms that are usually transient.

- Oppositional defiant disorder is characterized by a behavioral pattern of disobedience, hostility, defiance, and negativity toward people in authority. The behaviors are usually not violent nor do they cause severe harm, and they often occur only in certain contexts. Some people with oppositional defiant disorder go on to develop conduct disorder; if an individual's behaviors meet the criteria for both oppositional defiant disorder and conduct disorder, only conduct disorder is diagnosed.

continued on next page

- Attention-deficit/hyperactivity disorder (ADHD) is characterized by inattention, hyperactivity, and/or impulsivity. The inattentive type of ADHD is associated with academic problems, whereas the hyperactive/impulsive type is associated with disruptive behaviors, accidents, and rejection by peers.
- Criticisms of the DSM-IV-TR diagnostic criteria for ADHD include the difficulty in applying the criteria to adults, the arbitrariness of the age cutoff for the onset of symptoms, and failure to acknowledge different symptoms in females.
- Oppositional defiant disorder, conduct disorder, and ADHD are highly comorbid, making it difficult to sort out factors that contribute uniquely to one of the disorders.
- Neurological factors that contribute to ADHD include frontal lobe problems (which lead to the symptoms of inattention, impaired executive function and memory difficulties). Too little dopamine and imbalances in other transmitters may also play a role. Genes also contribute to ADHD and conduct disorder, in part by affecting temperament.
- Psychological factors that are associated with ADHD include low self-esteem and difficulty recognizing facial expressions of anger and sadness. People with oppositional defiant disorder and conduct disorder tend to have either low self-esteem or overly high self-esteem, are relatively unresponsive to the threat of punishment, and exhibit high levels of emotional distress and poor frustration tolerance.
- Social factors that contribute to ADHD include parents' not giving children enough credit for their positive behaviors. For oppositional defiant disorder and conduct disorder, social factors include abuse, neglect, inconsistent discipline, and lack of positive attention.
- Treatment targeting neurological factors in ADHD involves medication—typically methylphenidate or atomoxetine.

Treatments targeting psychological factors in ADHD, oppositional defiant disorder, and conduct disorder may use behavioral methods—especially reinforcement programs—to increase a person's ability to tolerate frustration and to delay reward, and cognitive methods to enhance social problem-solving ability. Treatments that target social factors in all three disorders include group therapy and comprehensive treatments such as contingency management, parent management training, and multisystemic therapy.

Making a Diagnosis

- Reread Case 14.5 about Brad, and determine whether or not his symptoms meet the criteria for conduct disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision? How severe do you consider his symptoms to be?
- Reread Case 14.6 about Danny, and determine whether or not his symptoms meet the criteria for oppositional defiant disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 14.7 about Edward Hallowell, and determine whether or not his symptoms meet the criteria for attention-deficit/hyperactivity disorder. Specifically, list which criteria apply and which do not. Which type(s) of symptoms does he seem to have? If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Other Disorders of Childhood

Children can exhibit a wide variety of odd or unusual behaviors that in and of themselves do not necessarily indicate psychopathology:

- Many children become anxious (temporarily) about separating from loved ones such as parents, particularly during early childhood and adolescence. Younger children may put up a fuss about being dropped off at school; older children may “freak out” about going away from home for the summer.
- Some children learn to speak and understand language quickly; others learn verbal communication skills more slowly.
- Children may go through phases that involve odd eating habits such as being picky eaters or occasionally chomping on a crayon.
- Children who have been toilet-trained can have accidents and “go” in places other than the toilet.

- Some children may, from time to time, exhibit repetitive movements, such as abnormally frequent eye blinking or repetitive vocal sounds such as throat clearing or odd noises.

These behaviors or constellations of behaviors are common enough to be considered normal patterns of infancy, childhood, and adolescence, but sometimes they may indicate any of a number of disorders. In the following sections we discuss the circumstances in which such behaviors would lead a clinician to diagnose a disorder. First, we'll explore an anxiety disorder that most typically arises in children—*separation anxiety disorder*. Then, we'll briefly review other types of disorders that can arise in children. Most of these disorders come to the attention of a pediatrician, who may treat the problem or, if needed, recommend a specialist; depending on the nature of the problem, the pediatrician might refer the child to a speech therapist, urologist, nutritionist, gastroenterologist, mental health clinician, or some other type of specialist.

Separation Anxiety Disorder

Although anxiety disorders form a distinct category in DSM-IV-TR (see Chapter 7), one anxiety disorder is placed among disorders pertaining to infancy, childhood, and adolescence because DSM-IV-TR specifies that it must begin in childhood. That disorder is **separation anxiety disorder**, which is characterized by excessive anxiety about separation from home or from someone to whom the child has become attached. In this section the word *parent* refers to the individual from whom the child fears separation; that individual may be the mother, father, some other family member, caretaker, or other person involved in the child's life. We'll examine separation anxiety disorder in detail, then turn to its causes and treatment.

What Is Separation Anxiety Disorder?

During different phases of development, an infant or toddler will normally become distressed on separating (or even thinking about separating) from a parent. To qualify for a diagnosis of separation anxiety disorder, the anxiety, distress, or impaired functioning must be excessive and must be exhibited over a period of at least 4 weeks (see Table 14.16).

Separation anxiety is more than a child's getting upset about temporarily saying goodbye to a parent. Children with separation anxiety disorder may become so homesick when away from home that activities—such as a sleepover at a friend's or a stay at overnight camp—are interrupted in order to return home. Or these children may want to know the parent's whereabouts at all times, using a cell phone to make frequent contact during any physical separation. And when away from the parent, they may also manifest physical symptoms of anxiety (see Chapter 7): dizziness, stomachaches, nausea and vomiting, and feeling faint (American Psychiatric Association, 2000). When the disorder emerges in children younger than 6 years old, the clinician can specify "early onset."

Some children with separation anxiety disorder fear that they will get permanently "lost" from their parents, and their dreams have similar themes. And like people with agoraphobia (see Chapter 7), they may be unable to leave the house alone (at an age when it would be appropriate to do so) or even to be in their room alone. Such children often try to stay within a few feet of the parent, moving from room to room as the parent moves from room to room. At bedtime, they may be unable to fall asleep unless someone else is in the room with them, and during the night, they may crawl into bed with parents or a sibling. If parents lock their bedroom door at night, the child may sleep on the floor right outside the door. If children with this disorder are separated from their parent, they may have persistent

Separation anxiety disorder

A psychological disorder that typically arises in childhood and is characterized by excessive anxiety about separation from home or from someone to whom the individual has become attached.

Table 14.16 ▶ DSM-IV-TR Diagnostic Criteria for Separation Anxiety Disorder

- A.** Developmentally inappropriate and excessive anxiety concerning separation from home or from those to whom the individual is attached, as evidenced by three (or more) of the following:
- (1) recurrent excessive distress when separation from home or major attachment figures occurs or is anticipated;
 - (2) persistent and excessive worry about losing, or about possible harm befalling, major attachment figures;
 - (3) persistent and excessive worry that an untoward event will lead to separation from a major attachment figure (e.g., getting lost or being kidnapped);
 - (4) persistent reluctance or refusal to go to school or elsewhere because of fear of separation;
 - (5) persistently and excessively fearful or reluctant to be alone or without major attachment figures at home or without significant adults in other settings;
 - (6) persistent reluctance or refusal to go to sleep without being near a major attachment figure or to sleep away from home;
 - (7) repeated nightmares involving the theme of separation;
 - (8) repeated complaints of physical symptoms (such as headaches, stomachaches, nausea, or vomiting) when separation from major attachment figures occurs or is anticipated.
- B.** The duration of the disturbance is at least 4 weeks.
- C.** The onset is before age 18 years.
- D.** The disturbance causes clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.
- E.** The disturbance does not occur exclusively during the course of a Pervasive Developmental Disorder, Schizophrenia or another Psychotic Disorder [Chapter 12] and, in adolescents and adults, is not better accounted for by Panic Disorder with Agoraphobia [Chapter 7].

fantasies about reuniting. Also, like individuals with generalized anxiety disorder (see Chapter 7), they may have recurrent fears about harm befalling their parent or themselves, as JC did, in Case 14.8. Table 14.17 lists additional facts about separation anxiety disorder.

CASE 14.8 ▶ FROM THE OUTSIDE: Separation Anxiety Disorder

JC is a 9-year-old boy who lives with his mother and attends the third grade, where he is an A student. During the last 2 weeks, he has refused to go to school and has missed 6 school days. He is awake almost all night worrying about going to school. As the start of the school day approaches, he cries and screams that he cannot go, chews holes in his shirt, pulls his hair, digs at his face, punches the wall, throws himself on the floor, and experiences headaches, stomachaches, and vomiting. If he attends school, he is less anxious until bedtime. As his separation anxiety has increased, he has become gloomy, has stopped reading for fun, and frequently worries about his mother's tachycardia [rapid heart rate].

JC was seen once by a psychiatrist at age 3 years for problems with separation anxiety. He did well in preschool and kindergarten. He was seen at a community mental health center during the first grade for school refusal, but did well again during the second grade. In addition to having recurrent symptoms of separation anxiety disorder, he is phobic of dogs, avoids speaking and writing in public, and has symptoms of generalized anxiety disorder and obsessive-compulsive disorder. His mother has a history of panic disorder.

(Hanna, Fischer, & Fluent, 2006, pp. 56–57)

Table 14.17 ▶ Separation Anxiety Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> • About 4% of adults experienced separation anxiety disorder in childhood (Shear et al., 2006). • Separation anxiety disorder is the most prevalent anxiety disorder among children.
Onset
<ul style="list-style-type: none"> • As required by DSM-IV-TR, the disorder must emerge before an individual is 18 years old, although it can begin as early as the preschool years. • Separation anxiety disorder may emerge after some type of stressful event, such as a move, the death of a pet, or the illness of a relative.
Comorbidity
<ul style="list-style-type: none"> • Children with separation anxiety disorder are more likely to experience other anxiety disorders than are children in the general population (Brückl et al., 2006; Verduin & Kendall, 2003).
Course
<ul style="list-style-type: none"> • Symptoms often wax and wane. • As the child gets older, symptoms tend to lessen; at some point before adulthood, most individuals no longer meet the criteria for the disorder (Foley, Pickles et al., 2004; Shear et al., 2006).
Gender Differences
<ul style="list-style-type: none"> • In the general population, more females than males have this disorder; however, comparable numbers of males and females with this disorder are treated as outpatients.
Cultural Differences
<ul style="list-style-type: none"> • Different ethnic groups and cultures have different norms about what constitutes appropriate responses to separation in children, which can affect parents' inclination to perceive a separation problem and create different thresholds for diagnosis across cultures.

Distinguishing Between Separation Anxiety Disorder and Other Disorders

As they did for JC, the symptoms of separation anxiety disorder can overlap with those of generalized anxiety disorder and social phobia. Both separation anxiety disorder and generalized anxiety disorder involve worries that are difficult to control, such as a fear that family members may be harmed. With separation anxiety disorder, however, the worries are restricted to separation from the parent; with generalized anxiety disorder, the worries involve a variety of topics, most of which are unrelated to separation issues. Similarly, although both social phobia and separation anxiety disorder may involve a reluctance to leave the house (and attend school), with social phobia, the fear is about performing or being evaluated by others.

When separated from the parent, children with separation anxiety disorder may exhibit symptoms of various other disorders. For instance, a child or adolescent with separation anxiety disorder may, on occasion, have panic attacks when forced to separate from the parent; however, the attacks do not indicate panic disorder unless the child or adolescent comes to fear having additional panic attacks. In addition, such children may appear depressed—seeming sad, apathetic and withdrawn—and have difficulty concentrating. In fact, some may become clinically depressed. Children with this disorder worry about death and may have persistent fears of monsters, kidnappers, or other harmful figures or acts, particularly when alone. They may even report that no one loves them—perhaps because their parents do not allow them to sleep in the parents' bed or because the parents force them to attend school. When forced to separate from the parent, children with separation anxiety disorder may get angry and hit other people. Parents, siblings, teachers, and others may report that a child with separation anxiety disorder is particularly needy

or “high maintenance,” which can lead to tension and frustration for all concerned. In some cases, the child’s behavior may resemble that of those with oppositional defiant disorder; however, children with separation anxiety disorder, unlike those with oppositional defiant disorder, generally comply with requests that do not require them to be separated from the parent.

Finally, we note that refusal to attend school is not always caused by separation anxiety disorder, however. It may arise because of a mood disorder, social phobia, or oppositional defiant disorder. Clinicians must thoroughly evaluate the reasons for the school refusal before diagnosing separation anxiety disorder.

Understanding Separation Anxiety Disorder

Separation anxiety disorder most commonly arises in children who are part of tight-knit families (American Psychiatric Association, 2000). Separation anxiety disorder is more common among first-degree relatives (parents and siblings) than in the general population, and the disorder is considered to be moderately heritable (Cronk et al., 2004). However, the heritability probably reflects a heritability of anxiety in general: Separation anxiety is more common among children whose mothers have panic disorder than among children whose mothers don’t have that disorder (Cronk et al., 2004).

But other factors create feedback loops: Tight-knit families may reinforce behaviors associated with anxiety about separation and may punish behaviors associated with actual separation. If so, then children in such families who have temperaments that are high in harm avoidance and reward dependence may be especially vulnerable, because they will be relatively responsive to reward and punishment. Moreover, separation anxiety disorder is more common in children whose fathers are absent (Cronk et al., 2004), perhaps because that absence leads the child to have a heightened fear of losing the remaining parent.

Treating Separation Anxiety Disorder

As with other anxiety disorders, treatment of separation anxiety disorder may involve CBT (with exposure and cognitive restructuring; see Chapter 7). Family therapy is often another component of treatment; the therapist identifies any family patterns that maintain the disorder and helps parents change their interaction patterns to encourage and reinforce their child for engaging in appropriate separation behaviors (Siqueland, Rynn, & Diamond, 2005).

Other Types of Disorders of Childhood, in Brief

Let’s now consider four subcategories of DSM-IV-TR disorders that typically arise in childhood: *communication disorders*, *feeding and eating disorders*, *elimination disorders*, and *tic disorders*. Disorders in these subcategories involve behaviors that are on an extreme end of a continuum, and thus represent abnormal rather than normal behaviors.

Communication Disorders

Some children evidence **communication disorders**, which are disorders characterized by significant problems in understanding language or in expressing themselves with language. (Children with hearing problems are not considered to have problems in understanding language unless they have clear difficulty learning sign language or other forms of language that do not require hearing.) A mental health clinician may be asked to help determine whether a child’s apparent difficulty comprehending language or expressing himself or herself is abnormal—outside the normal range—and, if so, whether a disorder other than a communication disorder might better account for the problems. For instance, a child might willfully refuse to speak or appear to misunderstand others (oppositional defiant disorder) or might be so anxious that he or she is “scared speechless.” Alternatively, a child might exhibit problems with coherently expressing himself or herself because of childhood-onset schizophrenia,

Communication disorders

A set of psychological disorders characterized by significant problems in understanding language or using language to express oneself.

a pervasive developmental disorder, mental retardation, or another disorder (American Psychiatric Association, 2000).

Feeding and Eating Disorders

Feeding and eating disorders are characterized by problems with eating or with feeding in the case of infants or young children whose diet consists entirely or mainly of liquids, such as formula or milk (American Psychiatric Association, 2000). Disorders in this subcategory include those that arise when a child does not eat enough (and so either loses weight or fails to gain adequate weight), disorders that lead the child to exhibit bizarre eating habits (such as eating nonfood objects, including dirt), as well as the eating disorders anorexia nervosa and bulimia nervosa (discussed in Chapter 10).

When the eating problem results from a medical problem or another psychological disorder, the diagnosis of a feeding or eating disorder is not made. Mental health clinicians may be asked to help determine whether feeding or eating problems arise from another psychological disorder, such as depression, anxiety, or oppositional defiant disorder, or from other causes. Mental health clinicians may also treat the child with a feeding or eating disorder and his or her family.

Elimination Disorders

Humans are not born knowing how to use the toilet; we must learn to do so. Most children learn by the age of 5 years, although they may have occasional accidents. But some children who are 5 years old or older do not routinely use the toilet appropriately to urinate or defecate, indicating an **elimination disorder**.

DSM-IV-TR includes two types of elimination disorders. **Encopresis** is the elimination disorder characterized by a child's persistently defecating in improper locations—neither in a toilet nor in a diaper (American Psychiatric Association, 2000). Encopresis often arises, paradoxically, as the result of constipation (Loening-Baucke, 1996): The colon and large intestine become full of hard stool, which makes bowel movements painful; children may then put off defecating as long as possible, which makes the constipation worse. The intestines cannot function properly because they are so full of stool (Partin et al., 1992), and the passage of feces becomes uncontrolled as looser stool from the small intestine leaks out around the mass of stool in the large intestine, colon, and rectum. Parents may then think their child is willfully refusing to use the toilet or has diarrhea, even though the real problem is the opposite—a large, hard stool that is difficult to pass. Encopresis that results from hard stool is often resolved through changes in diet, such as increasing the child's intake of fluids and high-fiber foods.

Enuresis is another elimination disorder, which is characterized by a child's persistently urinating in bed or into his or her clothes; nighttime enuresis, or bed-wetting, is common: Approximately a tenth of children between 5 and 16 years old wet their beds, although not necessarily nightly (Mellon & McGrath, 2000). As children age, this problem becomes less common. Nighttime enuresis usually involves abnormal sleep patterns that cause children to sleep so deeply that they are not aware of the sensations of a full bladder or cannot rouse themselves to get out of bed and get to the bathroom (Nield & Kamat, 2004).

The most successful treatment for enuresis is based on behavioral principles and uses a bed-wetting alarm, as shown in Figure 14.6 (Mellon & McGrath, 2000; Mikkelsen, 2001): This treatment helps the child learn to control his or her bladder at night (some models of the equipment, such as that in Figure 14.6, also work for daytime enuresis). The alarm goes off immediately after its sensor (attached to underwear) detects wetness. Initially, the child wakes up from the alarm *after* wetting the bed but is instructed to try to urinate in the toilet after being awakened by the alarm's going off. With motivation and repeated experience, the child learns to wake up increasingly earlier in the process of bed-wetting; within 6 months (but often in less time), the child usually learns to wake up and go to the bathroom

Feeding and eating disorders

A set of psychological disorders characterized by problems with feeding or eating.

Elimination disorders

A set of psychological disorders characterized by inappropriate urination or defecation.

Encopresis

An elimination disorder characterized by a child's persistent defecation in improper locations—neither in a toilet nor in a diaper.

Enuresis

An elimination disorder characterized by a child's persistent urination in bed or into his or her clothes.

Figure 14.6

14.6 ▶ Behavioral Treatment of Enuresis

A bed-wetting alarm is the treatment of choice for nighttime enuresis. In the model shown here, the sensor immediately detects any wetness, triggering the alarm, which is near enough to the child's ear that it will probably wake the child up when it goes off. Although initially the child wakes up after wetting the bed, with motivation and experience, he or she will learn to wake up increasingly closer in time to the release of urine. Soon thereafter, the child becomes able to wake up *before* urine is released and thus urinate in the toilet.

before urinating in the bed. That is, the child learns to detect the sensations of a full bladder even during sleep.

Although children may willfully refuse to use the toilet (which could be a symptom of oppositional defiant disorder; Christophersen, 1994) or have severe anxiety about using the toilet, both enuresis and encopresis usually arise from biological factors. Consultation with the child's pediatrician and implementation of the recommended strategies often resolve these disorders. Children with elimination problems may come to the attention of a mental health professional because the parents are worried not only about the problem itself but also that it may be a sign of another type of problem, such as oppositional defiant disorder, significant anxiety, or sexual abuse (perhaps by a child care provider).

Tic Disorders

A **tic** is rapid but repetitive involuntary movement or vocalization. Many people develop some kind of tic—they may have an episodic but persistent eye blink or shoulder shrug (motoric tics), or a recurrent “hmmm” of throat clearing or grunting sound (vocal tics). Tics are relatively common in children, but a **tic disorder** may be diagnosed when the tic (motor or vocal) is persistent and occurs many times a day on most days. In fact, up to 12% of children between 6 and 15 years old have a tic disorder at some point in their lives (Khalifa & von Knorring, 2003; Zhu et al., 2003).

One tic disorder is *Tourette's disorder* (also referred to as *Tourette syndrome*), named for the psychiatrist Gilles de la Tourette (1857–1904), who first described the constellation of symptoms. **Tourette's disorder** involves recurrent motoric *and* vocal tics. A rare type of vocal tic is the involuntary shouting of obscenities (referred to as *coprolalia*); only 10% of people with Tourette's disorder exhibit coprolalia (American Psychiatric Association, 2000).

Tic disorders are generally evaluated and treated by a neurologist. Children with these disorders can come to the attention of a mental health professional because parents may be concerned that the symptoms either represent willful oppositional behavior (as in oppositional defiant disorder) or are a manifestation of anxiety.

A tic may be difficult to distinguish from a stereotyped behavior that arises as part of a pervasive developmental disorder. However, stereotypies generally seem intentional and rhythmic, and they appear to soothe the individual exhibiting the behavior. In contrast, tic behaviors generally arise in clusters, and although they may sometimes feel voluntary, they are typically involuntary. Tics can also be difficult to distinguish from compulsions, especially if comorbid obsessive-compulsive disorder (OCD) is present. However, the compulsive behaviors of OCD are usually more elaborate and also more normal-seeming than a tic, and they are associated with corresponding obsessions. Vocal tics should be distinguished from the psychotically disorganized speech that is associated with schizophrenia: In the absence of other disorganized or psychotic behavior, a tic disorder is the more likely diagnosis.

Depending on the individual and the type and severity of tics, the effects can range from no distress or impaired functioning to severe distress and/or impaired functioning. Young children may not be aware of their tics and usually do not experience distress or impaired functioning, in part because their peers do not call attention to their problem. For older children and adults, the more noticeable the tics, the more social rejection they may experience and the more self-conscious and ashamed they are likely to become, perhaps leading them to avoid social interactions whenever possible. Frequent tics or those that involve complex behaviors (such as deep knee bends) may interfere with normal functioning. In such cases, medication for the tic disorder may decrease the frequency and intensity of the symptoms (Davies et al., 2006; Shavitt et al., 2006). Behavioral treatment for tics may help patients increase their ability to control the behaviors for short periods of time (Carr & Chong, 2005; Cook & Blacher, 2007; Phelps, Brown, & Power, 2002).

Tic disorders

A set of disorders characterized by persistent tics (motor or vocal) that occur many times a day on most days.

Tourette's disorder

A tic disorder characterized by recurrent motoric and vocal tics; also referred to as *Tourette syndrome*.

Key Concepts and Facts About Other Disorders of Childhood

- Separation anxiety disorder is characterized by excessive anxiety about separation from home or from someone to whom the child is strongly attached. Separation anxiety disorder is moderately heritable and is more likely to arise in tight-knit families, whose members may inadvertently reinforce behaviors associated with separation anxiety and punish behaviors associated with actual separation. Separation anxiety disorder is treated with methods used to treat other anxiety disorders: CBT that includes exposure and cognitive restructuring, along with family therapy.
- Communication disorders are characterized by problems in understanding or using language.
- Feeding and eating disorders are characterized by problems with attaining or maintaining adequate weight and nutrition or by bizarre eating habits.
- The elimination disorders are enuresis and encopresis, which are characterized, respectively, by accidental or intentional failure to urinate and failure to defecate appropriately in a toilet.
- Tic disorders are characterized by persistent motor or vocal tics. Tourette's disorder involves recurrent motoric and vocal tics.

Making a Diagnosis

- Reread Case 14.8 about JC, and determine whether or not his symptoms meet the criteria for separation anxiety disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

SUMMING UP

Summary of Mental Retardation

The diagnosis of mental retardation requires both an IQ score at or below 70 *and* impaired daily functioning. The four levels of mental retardation are mild, moderate, severe, and profound. Some people with mental retardation—particularly at the severe or profound level—may have difficulty communicating verbally.

Neurological factors are the primary direct cause of most cases of mental retardation—usually a genetic abnormality or prenatal exposure to a teratogen such as alcohol. In turn, the genetic abnormality or teratogen alters brain structure and function.

Although mental retardation cannot be cured, many types can be prevented, including those due to PKU and lead poisoning. Interventions are designed to improve the person's functioning by increasing his or her communication and daily living skills. Legally, children with mental retardation are entitled to special education and related services, tailored to their individual needs through an IEP.

Thinking like a clinician

Clare just graduated from college and started working in a center for adults with various intellectual disabilities. She is trying to get to know each client—his or her strengths and

weaknesses. The clients with mental retardation are classified in the moderate to severe range. Based on what you've learned, what can—and can't—you assume about those clients? Why might people with mild or profound mental retardation not be at the center?

Summary of Pervasive Developmental Disorders

Pervasive developmental disorders involve two types of problems: (1) significant deficits in communication and social interaction skills, and (2) stereotyped behaviors or narrow interests. Disorders in this category are autistic disorder, Asperger's disorder, childhood disintegrative disorder, and Rett's disorder.

Autistic disorder (or simply, autism) is characterized by significant problems with communication, social interactions, and language use. Individuals with autism are oblivious to other people and do not pay attention to or understand basic social rules and cues. They may have extremely narrow interests involving repetitive play. Many people with autism also have comorbid mental retardation when tested with conventional intelligence tests; on tests that do not rely on verbal abilities, however, people with autism tend to score in the average range or higher. In addition, some people with autism have unique skills.

Asperger's disorder is characterized by problems that are similar to—though less severe than—those associated with autism. With Asperger's, however, language and cognitive development are in the normal range.

Neurological factors that underlie autism include abnormal connections and communication among different brain areas, in particular, between the frontal lobe and the rest of the brain. Genes play a role in the development of autism and Asperger's. Psychological symptoms of autism include deficits in shifting attention and in mental flexibility, and problems in using a theory of mind. People with Asperger's have less severe problems with their theory of mind than people with autism. Social symptoms include problems in recognizing emotion in the voices or faces of others and in understanding the give and take of social communication.

Interventions for autism include medication for comorbid disorders or symptoms of anxiety, agitation, and aggression. Treatment for autism that targets psychological factors includes applied behavior analysis to modify maladaptive behaviors. Treatments that target psychological and social factors focus on teaching the individual to communicate, to recognize conventional social cues, to read the emotional expressions of others, and how to initiate and respond in social situations.

In contrast to autism and Asperger's disorder, childhood disintegrative disorder is characterized by normal development up to at least 2 years of age, followed by a profound loss of communication skills, normal types of play, and bowel control.

Rett's disorder also involves the loss of skills already mastered, but the onset of the disorder occurs between 5 months and 2 years of age. Mental retardation always accompanies Rett's disorder, which affects only females.

Thinking like a clinician

The center where Clare works also has clients with pervasive developmental disorders. Based on what you have learned, what is the most important information that Clare should know about people with pervasive developmental disorders, and why? What particular pervasive developmental disorders would be most and least likely to be seen in people who need the type of care that Clare's workplace provides? How might Clare use her knowledge about pervasive developmental disorders—and autism in particular—when she is working with the center's clients?

Summary of Learning Disorders

A learning disorder is characterized by a substantial disparity between an individual's performance on a standardized test and the expected level of performance based on the individual's age, intelligence, and education level. DSM-IV-TR includes three types of learning disorders: reading disorder (dyslexia), mathematics disorder, and disorder of written expression.

Genes contribute to learning disorders. Dyslexia appears to result from disruptions in brain systems that process language and in brain systems that process visual stimuli. Motivation and social support influence an individual's ability to overcome and compensate for a learning disorder.

Treatment for learning disorders may involve accommodations and services mandated by IDEA. Various cognitive techniques can help a person learn to compensate for a learning disorder.

Thinking like a clinician

Nikhil recently graduated from college and is about to start working in the *Teach for America* program. He's been assigned to teach at an inner city school. Nikhil was a math major in college and doesn't know much about learning disorders. However, he was a peer tutor in college and saw that some people had a *really*

hard time understanding different elements of math. Based on what you've read, what information should Nikhil know (and hopefully will be taught as part of his training) about learning disorders before he walks into a classroom, and why should he learn this?

Summary of Disorders of Disruptive Behaviors and Attention

Conduct disorder is characterized by a violation of the basic rights of others or of societal norms that are appropriate to the individual's age. The disorder may begin in childhood or adolescence. Conduct disorder is commonly comorbid with ADHD and substance use or abuse.

Childhood-onset conduct disorder with callous and unemotional traits has the highest heritability among the various types of conduct disorder. Individuals with this type of conduct disorder often have more severe symptoms. People with childhood-onset conduct disorder *without* callous and unemotional traits are less aggressive, although they are likely to be aggressive impulsively, in response to (mis)perceived threats. Adolescent-onset conduct disorder tends to involve mild symptoms that are usually transient.

Oppositional defiant disorder is characterized by a behavioral pattern of disobedience, hostility, defiance, and negativity toward people in authority. The behaviors are usually not violent nor do they cause severe harm, and they often occur only in certain contexts.

Attention-deficit/hyperactivity disorder (ADHD) is characterized by inattention, hyperactivity, and/or impulsivity. The inattentive type of ADHD is associated with academic problems, whereas the hyperactive/impulsive type is associated with disruptive behaviors, accidents, and rejection by peers. Criticisms of the DSM-IV-TR diagnostic criteria for ADHD include the difficulty in applying the criteria to adults, the arbitrariness of the age cutoff for the onset of symptoms, and failure to acknowledge different symptoms in females. Oppositional defiant disorder, conduct disorder, and ADHD are highly comorbid, making it difficult to sort out factors that contribute uniquely to one of the disorders.

Neurological factors that contribute to ADHD include frontal lobe problems (which lead to the symptoms of inattention, impaired executive function, and memory difficulties). Too little dopamine, and imbalances in other transmitters may also play a role. Genes also contribute to ADHD and conduct disorder, in part by affecting temperament.

Psychological factors that are associated with ADHD include low self-esteem and

difficulty recognizing facial expressions of anger and sadness. People with oppositional defiant disorder and conduct disorder tend to have either low self-esteem or overly high self-esteem, are relatively unresponsive to the threat of punishment, and exhibit high levels of emotional distress and poor frustration tolerance.

Social factors that contribute to ADHD include parents' not giving children enough credit for their positive behaviors. For oppositional defiant disorder and conduct disorders, social factors include abuse, neglect, inconsistent discipline, and lack of positive attention.

Treatment targeting neurological factors in ADHD involves medication—typically methylphenidate, or atomoxetine. Treatments targeting psychological factors in ADHD, oppositional defiant disorder, and conduct disorder may use behavioral methods—especially reinforcement programs—to increase a person's ability to tolerate frustration and to delay reward, and cognitive methods to enhance social problem-solving ability. Treatments that target social factors in all three disorders include group therapy and comprehensive treatments such as contingency management program, parent management training, and multi-systemic therapy.

Thinking like a clinician

Nikhil has some first-hand familiarity with oppositional defiant disorder and conduct disorder—he went to a large middle school and large high school, where some kids always acted up and got into trouble. And during high school and college, some of his friends and then one of his roommates had ADHD. Even though Nikhil may think he knows something about disruptive behavior disorders and ADHD, based on what you have read, what information about these disorders should he be given before he begins to teach, and why?

Summary of Other Disorders of Childhood

Separation anxiety disorder is characterized by excessive anxiety about separation from home or from someone to whom the child is strongly attached. Separation anxiety disorder is moderately heritable and is more likely to arise in tight-knit families. Separation anxiety disorder is treated with methods used to treat other anxiety disorders: CBT that includes exposure and cognitive restructuring, along with family therapy.

Communication disorders are characterized by problems in understanding or using language. Feeding and eating disorders are characterized by problems with attaining or

maintaining adequate weight and nutrition or by bizarre eating habits. The elimination disorders are enuresis and encopresis, which are characterized, respectively, by accidental or intentional failure to urinate and failure to defecate appropriately in a toilet. Tic disorders are characterized by persistent motor or vocal tics. Tourette's disorder involves recurrent motoric and vocal tics.

Thinking like a clinician

Nia is 12 years old and going through puberty. Lately she's been coming home right after school and staying home during the weekend, no longer hanging out with her friends. In fact, she's unhappy when her mother (her parents are divorced) leaves her alone to go shopping or to go out in the evening; sometimes she tearfully begs her mother not to leave, but won't—or can't—explain why she feels so upset. Based on what you have learned, how do you think Nia—and her mother—should proceed? Should they wait and hope

the symptoms pass or try to find out more? Explain your answer in detail.

Cognitive Disorders

Mrs. B. was an 87-year-old woman at the time that she was referred for neuropsychological testing. Mrs. B. wasn't always able to get to the toilet in time to urinate, her hearing and vision weren't as good as they had been, and, because of an inner-ear problem, she sometimes felt off-balance and fell. A neuropsychologist was asked to determine the nature of Mrs. B.'s problems—specifically the extent to which a cognitive disorder might account for at least some of her difficulties. The neuropsychologist noted that Mrs. B. required

“... assistance in several self-care activities (meal preparation, shopping, transportation, ambulation [moving around], dressing, and bathing), principally because of gait, balance, and sensory changes. . . . [She] had moved from another state several months earlier at the urging of her daughter, who had been receiving reports from neighbors and relatives that she was unable to care for herself or her home and was increasingly suspicious and argumentative. Her first residence in her new community was . . . a nursing home, but it soon became apparent that she was functioning at a higher level than other residents and she moved to a small board-and-care home [a small residential facility for elders who need round-the-clock help with daily functioning and personal care]. With only a few persons in the home and a low resident-to-staff ratio, this seemed a good arrangement for an older person who needed an intermediate level of assistance. Mrs. B. apparently thought otherwise.

“She often refused to admit staff to her room or to accept assistance with activities such as bathing, despite an unsteady gait and several recent falls. She had arguments with other residents that sometimes escalated into shouting matches. A private-duty companion was hired to assist her for several hours a day and to take her on excursions outside of the home. This was helping somewhat, but accusations and arguments continued at an unsettling rate. Mrs. B. sometimes seemed to forget plans that she had agreed to and was occasionally tearful and sad.”

(LaRue & Watson, 1998, pp. 6, 10)

What might account for Mrs. B.'s disruptive behavior and memory problems? One possibility is some type of cognitive disorder. According to DSM-IV-TR, **cognitive disorders** are a category of psychological disorders in which the primary symptom is significantly reduced mental abilities, relative to a prior level of functioning.

Impaired cognitive abilities are not unique to cognitive disorders. Many of the disorders discussed in previous chapters involve a change in cognitive functioning: People who are depressed or anxious

Diagnosing Mrs. B.'s Problems

Cognitive disorders

A category of psychological disorders in which the primary symptom is significantly reduced mental abilities, relative to a prior level of functioning.

can have impaired attention, concentration, and memory; those with a psychotic disorder have impaired perception and judgment; and substance abuse and dependence can lead to a wide variety of cognitive impairments. The cognitive changes associated with these disorders, however, are secondary to the other symptoms that characterize the disorders: depressed mood, anxiety and fear, psychotic symptoms, or behaviors related to substance abuse and dependence.

In contrast, with cognitive disorders, the changes in cognitive functioning—in mental processes—constitute the primary set of symptoms. Patients may (or may not) also exhibit disturbances in behavior, mood, or mental contents. Usually, the undesired cognitive changes arise from a medical disease such as Parkinson's disease, a medical condition such as a *stroke*, or the use of or withdrawal from a psychoactive substance (which may include exposure to a toxic substance). When substance use or withdrawal causes the cognitive symptoms, according to DSM-IV-TR, the symptoms must be in excess of those typically experienced with intoxication or withdrawal from a substance in order to be considered a cognitive disorder (American Psychiatric Association, 2000).

The three types of cognitive disorders discussed in this chapter are *delirium*, *amnesic disorder*, and *dementia*. Delirium involves impaired cognition and a marked change in awareness (as occurs when someone who is drinking alcohol doesn't recognize friends or drinks to the point of being in a stupor). Amnesic disorder involves impaired cognition that is confined to memory. Dementia involves impaired memory plus at least one other impaired cognitive function—such as perception, attention, or language use. Cognitive disorders are almost exclusively due to neurological factors.

In most cases, these disorders afflict older adults rather than younger adults. So, part of the job of diagnosing these disorders is to distinguish the symptoms of these disorders from changes that occur with normal aging. Let's first examine the changes in cognitive functioning that arise during the normal aging process, which will allow us to contrast these effects with those described in subsequent sections.

Normal Versus Abnormal Aging and Cognitive Functioning

The neuropsychologist assessing Mrs. B. needed to determine whether her disturbances in memory, mood, and behavior were normal for an 87-year-old, particularly one with a variety of medical problems. And, if her memory, mood, and behavior weren't in the normal range, given her circumstances, what, specifically, could account for her difficulties? The neuropsychologist initially assessed Mrs. B. using a clinical interview (discussed in Chapter 3), observing her as well as noting her responses to questions:

“Mrs. B. arrived promptly for her appointment, accompanied by her private-duty nurse. She was well-groomed and alert but ambulated slowly, leaning against the railing on the wall to maintain her balance; she was also unsteady on rising and standing from a chair. She was fluent and willing to talk at great length about her situation, although her speech was often repetitive and tangential. Mood was . . . positive during the interview. She denied hallucinations, delusions, or suicidal ideation but admitted to some depression, which she felt had improved somewhat on antidepressant medication. She was able to describe some aspects of her experience at the [nursing home] and gave several examples of the types of things that annoyed her at the current board-and-care home.”

(LaRue & Watson, 1998, p. 6)

Mrs. B. was able to remember aspects of her nursing home experience that she didn't like, but she forgot other types of information, such as upcoming plans to which she had agreed. In the normal course of events, however, various cognitive functions tend to decline with advancing age. Mental health clinicians must compare the individual's current cognitive functioning both to the person's prior abilities and to the normal changes in functioning that occur with age. Even healthy older adults have some cognitive deficits, compared to their younger counterparts,

and these must be taken into account when attempting to determine whether an older individual has a disorder. Thus, the neuropsychologist must assess whether Mrs. B.'s functioning has declined and, if so, whether this decline is beyond what occurs with the normal aging process. In this section, we examine what happens to cognitive functioning during normal aging and then examine the neurological factors that can disrupt cognitive functioning.

Cognitive Functioning in Normal Aging

Most—though not all—aspects of cognitive functioning remain relatively stable during older adulthood. Let's first examine intelligence, which can be divided into two sets of abilities, or types of intelligence (Cattell, 1971): **Crystallized intelligence** relies on using knowledge to reason; such knowledge has “crystallized” from previous experience. Normally, crystallized intelligence, such as the ability to understand what various words mean, remains stable or increases with age, even among older adults; crystallized intelligence is often assessed through tests that measure verbal ability, and these tests often allow ample time for people to respond to questions. In contrast, **fluid intelligence** relies on the ability to create new strategies to solve new problems, without relying solely on information previously learned. Fluid intelligence relies on *executive functions*, which include the abilities to think abstractly, to plan, and to exert good judgment. Fluid intelligence is typically assessed with tests of visual-motor skills, problem solving, and perceptual speed (Salthouse, 2005); these tests usually are timed, and points are lost for taking “too long” to respond with the right answer. If Mrs. B. took such tests, even if she gave the correct answer, her scores would be lower if she took more than a “normal” amount of time. As adults age, they respond more slowly, and so their scores on most measures of fluid intelligence decline. Specifically, these kinds of test scores begin to decline noticeably at around age 55, with a more significant decline at around age 65 (Harvey, 2005a). When tests are not timed, however, the decline in fluid intelligence is less pronounced, particularly on tests that involve executive functioning (Jennings et al., 2007).

Of course, normal cognitive decline is always judged in relation to the individual's baseline. An older adult who starts out with a high IQ and has functioned well will probably be able to continue to function well even with the normal decline of aging. In contrast, the functioning of someone who has a lower IQ initially (such as in the low normal range, or an IQ of 85 or lower) will be affected more dramatically—perhaps to the point where his or her ability to function independently is curtailed (Harvey, 2005a).

Let's examine in more detail some of the specific mental processes that are affected by normal aging: memory, processing speed, attention, and executive functions.

Memory

Memory is not a single ability, and various aspects of it are affected in different ways by aging. We can distinguish between implicit and explicit memories. *Implicit memories* consist of unconscious stored information that guides a person to behave in certain ways. Classical and operant conditioning produce implicit memories; habits, such as those used by someone who is adept at cooking or trout fishing, are implicit memories. Implicit memories are not affected very much by aging (Fleischman et al., 2004). Older people often remember how to perform well-learned tasks such as driving or typing.

In contrast, *explicit memories* can be voluntarily brought to mind, as words or mental images. For example, remembering where you left your house keys, the name of your best friend, or the facts you learned earlier in this book relies on explicit memories. The elderly (generally considered to be people aged 65 and older; World Health Organization [WHO], 2009) tend to have problems with some aspects of explicit memories. In particular, they have problems in recalling stored explicit information. To *recall* information is to activate that information after voluntarily

Rick Gomez/Corbis

Aging normally only minimally affects crystallized intelligence, which relies on knowledge based on previous experience.

Crystallized intelligence

A type of intelligence that relies on using knowledge to reason; such knowledge has “crystallized” from previous experience.

Fluid intelligence

A type of intelligence that relies on the ability to create new strategies to solve new problems, without relying solely on information previously learned.

An older person may sometimes be unable to recall the name of a common object but be able to recognize the name if someone else says it. This and other normal aging-related cognitive changes do not usually impair daily functioning.

attempting to “look it up” in memory, and so to become aware of it. For instance, essay tests assess a person’s ability to recall information about a topic. In contrast, to *recognize* information requires first perceiving it and then comparing it to information stored in memory; if what you perceive matches something you’ve previously stored in memory, you’ve recognized the stimulus. For instance, multiple-choice tests assess a person’s ability to recognize a correct answer to a question.

Healthy older people often have little difficulty with recognition but do have problems with some aspects of recall. In particular, older people sometimes have trouble recalling the names of common objects on demand. Thus, they might say, “I went to the store to buy a ‘thingamajig’ this morning.” The person can describe the object or recognize the correct word when someone else says it, and he or she may even recall the correct word a few minutes later when talking about something else (Nicholas et al., 1985). In addition, the elderly often have trouble remembering the source of information—where or when they learned it (Schacter et al., 1991, 1997).

However, in spite of these difficulties, healthy older people can often recall temporarily forgotten names of common things when given cues or hints. Moreover, with normal aging, the ability to recall personal information is preserved; people can recall important episodes from their past.

Processing Speed, Attention, and Working Memory

Memory involves storing information and then later accessing it. Specific mental processes are used to store and access information, and these processes can take varying amounts of time. Older adults have a slower processing speed, so they generally learn new information at a slower rate, need more exposure to the to-be-learned material, and need more practice in retrieving the information after they have learned it. For these reasons, the elderly may be impaired when carrying out tasks that require rapid responses (Filitt et al., 2002; Salthouse, 2001). One explanation for the slowed processing that comes with advanced age is that the myelin sheaths coating the axons degrade or disappear, which then causes the neurons’ signals to dissipate, and hence communication among brain areas is impaired (Andrews-Hanna et al., 2007).

Attention involves selecting some information for more careful analysis: what a person pays attention to gets processed more fully than what he or she does not pay attention to. The ability to sustain attention or to divide attention sequentially among multiple tasks (known as *multitasking*) is also likely to decline as people age (Parasuraman, Nestor, & Greenwood, 1989). Thus, older adults may have a harder time performing tasks such as balancing a checkbook while talking on the phone.

Many tasks—as well as the tests used in neuropsychological assessments—require both sustained attention and the faster processing speed

Figure 15.1

15.1 ► Trail Making Test The Trail Making Test (Reitan, 1958), similar to this figure, involves connecting dots in a particular fashion—alternating numbers and letters in ascending and alphabetical order. The test-taker is to make a line from 1 to A, then from A to 2, from 2 to B, and so on.

typical of younger people. For instance, one test that requires both abilities is the *Trail Making Test* (Reitan, 1958), a timed test that requires the individual to connect dots in a particular sequence; one version involves dots with alternating numbers and letters, and test-takers are asked to connect the dots in ascending and alphabetical order (see Figure 15.1 for a similar task). The average 25-year-old takes 26 seconds to complete the task, whereas the average 72-year-old takes 70 seconds to complete it (Spren & Straus, 1998). Mrs. B. was not able to complete the test as instructed; she connected only the numbered dots and omitted the lettered dots entirely (LaRue & Watson, 1998).

If you tried our version of the Trail Making Test in Figure 15.1, you probably noticed that it's a bit of a mental juggling act. Such mental juggling is typical of tasks that rely on *working memory*. Working memory requires keeping information activated (so that you are aware of it) while operating on it in a specific way; for example, counting backwards by 3 from 100 requires working memory (holding in mind the number 100, subtracting 3, then holding in mind 97, subtracting 3, and so on). Working memory relies on the frontal lobes, and the key parts of frontal lobes don't operate as effectively in elderly people as they do in younger people—and hence the elderly typically have problems using working memory (De Beni & Palladino, 2004; Li, Lindenberger, & Silkeström, 2001).

In sum, normal aging typically leads to problems in recall, slower mental processing, difficulty sustaining high levels of attention and in dividing attention, and problems with working memory. These abilities are necessary for fluid intelligence, which usually declines with age but generally not enough to impair daily functioning. In contrast, crystallized intelligence, which includes recognition memory for vocabulary and memory for personal events, typically does not decline dramatically with age.

Psychological Disorders and Cognition

Contrary to popular belief, most older adults don't have a psychological disorder; in fact, older adults have the lowest prevalence of psychological disorders of any age group (American Psychological Association, Working Group on Older Adults, 1998). But when an older person does have a psychological disorder, its symptoms can impair cognitive functioning. Thus, before assuming that an individual's deteriorated cognitive functioning is due to a *cognitive* disorder—delirium, amnesic disorder, or dementia—the clinician must first determine whether the deterioration could be due to another psychological disorder. For instance, Mrs. B. had a history of depression and described herself as having a “hot temper” even as a young adult. Mrs. B.'s daughter described her mother “as always somewhat self-centered and suspicious of the motives of others, but this had worsened noticeably in recent years, to the point where she had been isolated within her own home,” which led to the move to the nursing home (LaRue & Watson, 1998, p. 6).

The neuropsychologist must determine whether Mrs. B.'s memory problems might reflect a psychological disorder such as depression. Let's briefly review the psychological disorders that most commonly diminish cognitive functioning in older adults: depression, anxiety disorders, and schizophrenia.

Depression

Older adults are less likely than their younger counterparts to be diagnosed with depression. When they are depressed, however, the symptoms often differ from those of younger adults: Older depressed adults have more anxiety, agitation, and memory problems (Segal, 2003). Thus, cognitive functioning is affected by depression both directly (memory problems) and indirectly (anxiety and agitation affect attention, concentration, and other mental processes; see Table 15.1). When depressed, a particular group of older adults is at high risk for suicide: Older White men who live alone have the highest suicide rate of any age group (WHO, 2002).

A mental health clinician must also determine whether symptoms of depression in an older person could be *caused* by a cognitive disorder: Some symptoms of depression, such as fatigue, may be caused by brain changes associated with a cognitive disorder (Puente, 2003). Mr. Rosen, in Case 15.1, was being treated for depression and experienced cognitive problems that may or may not have been related to his depression.

Table 15.1 ▶ Common Cognitive Deficits in Late-Life Depression

Information processing speed

- Slow to respond or initiate behavior; incomplete grasp of complex information (because of a lag in processing)

Attention and concentration

- Absentmindedness for daily activities, events, and appointments; tasks left incomplete; decreased attentiveness for reading or conversation, which can also disrupt memory

Executive function

- Difficulty with calculating, sequencing, multitasking, and other novel problem solving; inflexible behavior or thinking; perseverative or ruminative thinking; decline in organization and planning; indecisiveness, decreased initiation of behavior

Memory

- Forgetfulness and absentmindedness, but should improve with prompts, cues, or explicit memory aids

Source: Potter & Steffens, 2007. For more information see the permissions section.

CASE 15.1 ► FROM THE OUTSIDE: Normal Aging or Something More?

Maurice Rosen was 69 when he made an appointment for a neurological evaluation. He had recently noticed that his memory was slipping and he had problems with concentration that were beginning to interfere with his work as a self-employed tax accountant. He complained of slowness and losing his train of thought. Recent changes in the tax laws were hard for him to learn, and his wife said he was becoming more withdrawn and reluctant to initiate activities. However, he was still able to take care of his personal finances and accompany his wife on visits to friends. Although mildly depressed about his disabilities, he denied other symptoms of depression, such as disturbed sleep or appetite, feelings of guilt, or suicidal ideation.

Mr. Rosen has a long history of treatment for episodes of depression, beginning in his 20s. He has taken a number of different antidepressants and once had a course of electroconvulsive therapy. As recently as 6 months before this evaluation, he had been taking an antidepressant.

(Spitzer et al., 2002, p. 70)

Like Mr. Rosen, Mrs. B. had a history of depression and was taking antidepressant medication. However, the neuropsychologist who assessed Mrs. B.'s cognitive functioning determined that the difficulties she was having were not due to depression (LaRue & Watson, 1998).

Anxiety Disorders

Like depression, anxiety disorders are less common among older adults than among younger adults. The anxiety disorder most prevalent among older adults is generalized anxiety disorder (Segal, 2003). About 5% of older adults have generalized anxiety disorder, most often along with depression; in about half the cases, the anxiety disorder was not present when the individual was younger (Flint, 2005). The fears and worries that accompany generalized anxiety disorder can impair cognitive functioning, in part because they give rise to preoccupations and decreased attention and concentration.

Schizophrenia

Although not common, about 15% of people with schizophrenia have their first psychotic episode when older than 44 (Cohen et al., 2000). Schizophrenia can involve both positive symptoms (delusions and hallucinations) and negative symptoms, such as speaking minimally (alogia) and an absence of initiative (avolition; see Chapter 12); these symptoms can also arise with cognitive disorders.

Medical Factors That Can Affect Cognition

The typical older adult has one or more medical conditions that can diminish cognitive functioning. In this section we review medical problems that affect cognitive functioning and that can cause cognitive disorders—delirium, amnestic disorder, and dementia.

Diseases and Illnesses

Various physical diseases and illnesses can affect cognition—directly or indirectly. Some medical illnesses, such as encephalitis (a viral infection of the brain) and brain tumors, directly affect the brain and, in doing so, affect cognition. The specific cognitive deficits that arise depend on the particular features of the illness, such as the size and location of a brain tumor.

Some chronic diseases or illnesses indirectly affect cognition by creating pain, which can disrupt attention, concentration, and other mental processes. For example, arthritis can cause chronic pain, and the aftermath of surgery can cause acute pain. In addition, pain can interfere with sleep, which further impairs mental processes. The detrimental effects on cognition of some illnesses may be temporary, so

that cognitive functioning improves as the symptoms resolve or the pain recedes. In other cases, though, the person may never return to his or her prior level of functioning.

In still other cases, an older adult may *appear* to have impaired cognitive functioning but actually has undiagnosed or uncorrected sensory problems, such as hearing loss or vision problems. If someone chronically mishears what is said, he or she will seem “not with it” or “senile” when, in fact, the problem is simply that the individual thinks the topic of conversation is something other than what it actually is.

Stroke

A **stroke** (so named because it was originally assumed to be a “stroke of God”) is the interruption of normal blood flow to or within the brain (often because of an obstruction—such as a blood clot—in a blood vessel). The result is that part of the brain fails to receive oxygen and nutrients, and the neurons in that area die. The cognitive, emotional, and behavioral consequences of a stroke depend crucially on which specific group of neurons is affected; depending on their location, different deficits are produced. In the following sections, we briefly consider some of the more common deficits.

Aphasia

Aphasia is a problem in using language. (The word *aphasia* literally means “an absence of speech.”) Traditionally, there are two main types of aphasia, each named after a neurologist who first characterized it in detail. **Broca’s aphasia** is characterized by problems producing speech and often occurs after damage to part of the left frontal lobe. Patients with Broca’s aphasia speak haltingly, and their speech can be very telegraphic—consisting of only the main words. In addition, they typically don’t use grammar correctly; for example, these patients often omit words such as *and*, *or*, and *of*. In contrast, **Wernicke’s aphasia** is characterized by problems with both comprehension of language and production of meaningful utterances. This disorder often occurs after damage to part of the rear portions of the left temporal lobe. Although these patients may appear to speak fluently, they often order words incorrectly and sometimes make up nonsense words. For instance, when asked to describe his occupation prior to suffering a stroke, one patient with Wernicke’s aphasia said, “Never, now mista oyge I wanna tell you this happened when happened when he rent” (Kertesz, 1981, p. 73, as cited in Carlson, 1994, p. 517). Clinicians sometimes have difficulty distinguishing between schizophrenia and Wernicke’s aphasia. However, people with schizophrenia (except perhaps when extremely psychotic) can understand speech and name objects better than can patients with Wernicke’s aphasia (Mendez & Cummings, 2004).

Agnosia

Patients who have *agnosia* have difficulty understanding what they perceive, although neither their sensory abilities nor their knowledge about objects is impaired. Many forms of agnosia can arise, but two are most common. *Apperceptive agnosia* occurs when a person cannot organize visual input into objects and their spatial relations. As a consequence, a person with apperceptive agnosia cannot determine whether two shapes are the same or different and thus cannot copy a drawing. (This disorder may arise following carbon monoxide poisoning, which produces diffuse damage in the occipital lobe.) This disorder can lead to disorientation, which must be distinguished from disorientation that occurs with dementia (to be discussed shortly).

The other common form of agnosia, *associative agnosia*, occurs when a person can visually organize shapes appropriately, and hence can see objects, but cannot associate the shape with its meaning—and hence cannot understand what he or she is seeing. Thus, someone with associative agnosia is able to tell whether two objects are the same or different, and can copy a drawing of a stick figure, but doesn’t understand that the lines and circle of the stick figure represent a human. Here’s another example of the type of problems that arise with associative agnosia: One of

A stroke is an interruption of normal blood flow to the brain that causes neurons in that part of the brain to die. The effect of a stroke depends on its location in the brain and the size of the brain area that it affects. This image shows a colored MRI scan of the brain of a woman who had a stroke, with red indicating dead brain tissue and green indicating healthy tissue.

Simon Fraser / Royal Victoria Infirmary, Newcastle upon Tyne / Photo Researchers

Stroke

The interruption of normal blood flow to or within the brain, which results in neuronal death.

Aphasia

A neurological condition characterized by problems in producing or comprehending language.

Broca’s aphasia

A neurological condition characterized by problems producing speech.

Wernicke’s aphasia

A neurological condition characterized by problems comprehending language and producing meaningful utterances.

us (SMK) once saw a patient who could not name a comb when shown it but could say what color it was and could reach for it and hold it properly. Moreover, as soon as the patient felt the comb with his fingers, he could name it easily. The problem was not that he had forgotten the name or that he was unable to retrieve or say the name—rather, it was an inability to make the connection between (that is, to associate) the visual form and the appropriate information stored in memory (Farah, 2004; Kosslyn & Koenig, 1995). Clinicians must distinguish between this kind of problem with object recognition and the sort of disorientation that may accompany severe psychosis, as sometimes occurs with schizophrenia.

Apraxia

Another medical condition that can affect cognitive functioning is **apraxia** (Kosslyn & Koenig, 1995), which involves problems in organizing and carrying out voluntary movements even though the muscles themselves are not impaired. The problem is in the brain, not in the muscles. Apraxia can take a variety of forms; some patients have trouble with individual components of a series of movements (such as pinching thumb and forefinger to pick up a coin), whereas others have trouble sequencing movements (such as the movements necessary to light a candle, that is, taking out a match, striking it, and holding the flame to the wick). Clinicians must distinguish between such problems with voluntary movements and the avolition (difficulty initiating or following through with activities) that may accompany schizophrenia (noted in Chapter 12).

Head Injury

Cognitive disorders can arise from head injuries—which may result from a car accident, from a fall, or in a variety of other ways. The specific cognitive deficits that develop depend on the exact nature of the head injury. The same kinds of deficits that follow a stroke can also occur after a head injury.

Substance-Induced Changes in Cognition

We saw in Chapter 9 that some people take substances (including prescribed medications) to alter their level of awareness or their emotional or cognitive state. But medications or exposure to toxic substances can produce unintended changes in attention, memory, judgment, or other cognitive functions, particularly when a high dose is taken. In fact, older people are more sensitive to the effects of medications, and so a dose appropriate for a younger adult is more likely to have negative effects or side effects in an older adult (Mort & Aparasu, 2002). Even anesthesia for surgery can subsequently affect cognitive functioning (Thompson, 2003).

To determine whether psychological or medical disorders are causing an individual's decline in cognitive functioning, the clinician may take a number of steps (Harvey, 2005a; Rabin et al., 2006). Specifically, he or she may

- interview and observe the patient;
- speak with the patient's family or friends or someone else who knows the patient and his or her history;
- obtain a medical examination by an internist or neurologist;
- ask for laboratory testing to be performed, such as blood tests or neuroimaging tests;
- review the patient's recent and current medications;
- assess the patient's ability to function in daily life; and
- obtain neuropsychological testing to determine the specific cognitive abilities that are impaired.

All of these steps were taken when Mrs. B. was being diagnosed in order to determine the nature of her problems—her memory difficulties and her disruptive behaviors that made it difficult for her to live in supervised residential settings.

Apraxia

A neurological condition characterized by problems in organizing and carrying out voluntary movements even though the muscles themselves are not impaired.

Delirium

A cognitive disorder characterized by a disturbance in consciousness and changes in cognitive functioning, particularly in attention.

Key Concepts and Facts About Normal Versus Abnormal Aging and Cognitive Functioning

- Most aspects of cognitive functioning remain stable during the normal course of aging. However, fluid intelligence and the related abilities of processing speed, recalling verbal information on demand, maintaining attention, and multitasking do decline in older adults. But these declines do not generally impair daily functioning.
- Although older adults are less likely than younger adults to have a psychological disorder, the disorders that are most common among older adults are depression and generalized anxiety disorder. A small percentage of adults develop schizophrenia and have their first psychotic episode after the age of 44. These disorders can lead to impaired cognitive functioning that may superficially resemble symptoms of a cognitive disorder.
- Brain injury, most commonly from a stroke, can produce various cognitive deficits that may resemble those related to psychological disorders. Among the deficits that may follow a stroke or a head injury are aphasia (problems with producing

and comprehending language), agnosia (problems in interpreting what is perceived), and apraxia (problems in organizing and producing voluntary movements).

- Legally prescribed medications or illegal substances can alter awareness, emotional states, and cognitive functioning. A dose that is standard for a younger person can adversely affect an older adult.

Making a Diagnosis

- Reread Case 15.1 about Maurice Rosen, and determine whether or not his symptoms are probably the result of normal aging or might indicate a psychological disorder. Specifically, list which symptoms seem to result from normal aging and which ones may indicate a disorder. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Delirium

Mrs. B.'s cognitive difficulties emerged gradually over time. Although she forgot appointments, she never forgot—and was never confused about—who and where she was. Moreover, she did not experience unusual or rapid changes in consciousness or in the ability to focus her attention. If she had, these symptoms might have indicated that she was delirious, as are many residents of nursing homes who are 75 years old or older (American Psychiatric Association, 2000). In this section we look at delirium in detail.

What Is Delirium?

Delirium is characterized by two main symptoms: a disturbance in consciousness and changes in cognitive functioning, particularly in attention. These symptoms develop rapidly—over hours to days—and fluctuate within a 24-hour period. The disturbance in consciousness is evidenced by decreased awareness of the external environment; the person may appear “stoned” or seem to be focusing on internally generated stimuli, such as mental images. Attentional problems include difficulties in focusing on external stimuli as well as problems in sustaining and shifting attention. A delirious patient may have a hard time understanding a question, or may have trouble shifting attention to a new question and remain focused on the previous one. Alternatively, he or she may be distracted and unable to pay attention to any question.

These attentional problems can make it difficult for a clinician to interview the delirious patient; the clinician must infer the patient's mental state from his or her behavior and unusual responses and then seek information from family members or friends. The DSM-IV-TR diagnostic criteria are summarized in Table 15.2, and Case 15.2 describes one woman's experience with delirium.

Table 15.2 ▶ DSM-IV-TR General Diagnostic Criteria for Delirium

- A.** Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B.** A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C.** The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D.** There is evidence from the history, physical examination, or laboratory findings that the symptoms in Criteria A and B are (one or more of the below):
 1. Caused by medication;
 2. Caused by a general medical condition;
 3. Developed during substance intoxication;
 4. Developed during, or shortly after, a withdrawal syndrome.

CASE 15.2 ► FROM THE OUTSIDE: Delirium

A 74-year-old African American woman, Ms. Richardson, was brought to a city hospital emergency room by the police. She is unkempt, dirty, and foul-smelling. She does not look at the interviewer and is apparently confused and unresponsive to most of his questions. She knows her name and address, but not the day or the month. She is unable to describe the events that led to her admission.

The police reported that they were called by neighbors because Ms. Richardson had been wandering around the neighborhood and not taking care of herself. The medical center mobile crisis unit went to her house twice but could not get in . . . they broke into the apartment . . . and then found Ms. Richardson hiding in the corner, wearing nothing but a bra. The apartment was filthy. . . .

[Ms. Richardson was diabetic, and her diabetes was out-of-control when she was admitted to the hospital. They begin to stabilize her medically and decided to transfer her the next day to a medical unit. Before the transfer, she was interviewed by a psychiatrist, who noted:]

Her facial expression was still mostly unresponsive, and she still didn't know the month and couldn't say what hospital she was in. She reported that the neighbors had called the police because she was "sick," and indeed she had felt sick and weak, with pains in her shoulder; in addition, she had not eaten for 3 days. [Her mental state improved when the diabetes was treated.]

(Spitzer et al., 2002, pp. 13–14)

When delirious, individuals may also be disoriented, not knowing where they are or what the time, day, or year is; this was the case with Ms. Richardson in Case 15.2. Less frequently, when delirious, people may not know *who* they are. In addition, they may have difficulty speaking clearly, naming objects, or writing. The content of their speech may resemble that of someone in a manic episode: pressured and nonsensical, or flitting from topic to topic.

Delirious people may also experience perceptual alterations, including:

- *misinterpretations* (correctly perceiving a sensory stimuli but making the incorrect interpretation of what it is, such as correctly identifying the smell of smoke but incorrectly attributing the smell to a roaring fire rather than to an extinguished match);
- *illusions* (misperceiving an object, as in perceiving the form of a pair of pants crumpled on the floor as a dog); and
- *hallucinations* (seeing—or hearing—someone or something that isn't actually there).

The perceptual disturbances are most frequently visual. Delirious individuals may believe that their perceptual experiences are real and behave accordingly. Hallucinations that are threatening may make them afraid, and they may respond by attacking others. Sometimes people in a delirious state are injured while responding to their altered perceptions, and their behavior can appear bizarre. Because of the perceptual difficulties, such patients may not consent to appropriate treatment.

People experiencing delirium may also have problems with their sleep cycle, or they may become physically restless and agitated. Perceptual alterations are more likely when patients are in this state. Alternatively, delirious patients may exhibit the opposite pattern, becoming sluggish, with diminished physical activity; perceptual disturbances are less likely during this state. During a 24 hour period, a patient may shift between these two patterns. Emotions may run the gamut, rapidly shifting from elation and euphoria to depression, fear, anxiety, and apathy.

Delirium is most common among the elderly, the terminally ill, and patients who have just had surgery; it is not yet known why delirium is more likely among these groups, but it may arise from neurological changes related to aging that make

Table 15.3 ▶ Delirium Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Older adults are more likely than others to develop delirium. At any given time, 0.4% of adults over the age of 18 may be delirious; among those 55 years of age or older, the prevalence almost triples, to 1.1%. Among elderly patients in hospitals, 10–15% are delirious when admitted and 10–40% may be diagnosed with delirium during their stay. Among residents in nursing homes who are age 75 and older, up to 60% may be delirious at any point in time. Up to 80% of terminally ill patients will become delirious, particularly when they are close to death (Brown & Boyle, 2002).
Comorbidity
<ul style="list-style-type: none"> Delirium may occur along with another cognitive disorder or a substance-related disorder.
Onset
<ul style="list-style-type: none"> When delirium is caused by certain drugs, such as cocaine or hallucinogens (see Chapter 9), symptoms usually emerge within minutes to hours. When delirium arises from other substances, such as benzodiazepines, symptoms may take longer to emerge. Delirium can arise after head trauma, in which case symptoms often develop immediately.
Course
<ul style="list-style-type: none"> Symptoms of delirium typically fluctuate over the course of the day. For most people, symptoms completely subside within a few hours or days; for others, especially the elderly, symptoms may persist for months or longer. A shorter course occurs when the cause of delirium is contained and brief, as with substance intoxication. People who had relatively good health and cognitive functioning before their delirium began are likely to make a better recovery. People with previous episodes of delirium are more vulnerable to subsequent episodes.
Gender Differences
<ul style="list-style-type: none"> Among the elderly, men are more likely than women to become delirious.
Cultural Differences
<ul style="list-style-type: none"> Countries have different guidelines for diagnosing delirium, which can prohibit making meaningful comparisons across countries (Leentjens & Diefenbacher, 2006).
Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

the elderly more vulnerable to develop delirium. Table 15.3 provides additional information about delirium.

Symptoms of delirium can also occur with other disorders, which may make it difficult to provide a definitive—or even a tentative—diagnosis. The following symptoms may seem similar to those of delirium:

- *Psychotic symptoms.* In schizophrenia or a mood disorder with psychotic features, the psychotic elements (i.e., delusions and hallucinations) are often integral to the symptoms of the disorder. In contrast, in delirium, the aspects of symptoms that appear psychotic are not as systematic.
- *Mood, anxiety, or dissociative symptoms.* With mood, anxiety, or dissociative disorders, the symptoms of fear, anxiety, or dissociation are relatively stable and tend not to vary with cognitive symptoms. In contrast, with delirium, symptoms of fear, anxiety, or dissociation tend to fluctuate along with the cognitive symptoms, and attentional problems are prominent.

If the clinician has reason to suspect that the symptoms arise because of a medical condition, as in the case of Ms. Richardson, or substance use, delirium is a tentative diagnosis, pending physical or laboratory tests. In addition, the clinician

should take care when diagnosing delirium in people from another culture or a different background. Such individuals may respond to the clinician's questions in ways that suggest delirium, but the clinician should consider whether a patient's culture or background, along with anxiety or symptoms of other disorders, might better account for the apparent cognitive difficulties.

Understanding Delirium: A Side Effect?

Delirium can arise from ingestion of a substance, such as alcohol or a prescribed medication, or as a result of a medical condition, such as an infection.

Delirium That Arises From Substance Use

Delirium can arise from the effects of a psychoactive substance such as alcohol or a medication, or from withdrawal from such a substance. According to DSM-IV-TR, intoxication or withdrawal are considered to give rise to delirium only when the symptoms are significantly more severe than those that usually occur during intoxication or withdrawal. The symptoms must be severe enough that they require more than the usual attention and treatment provided to someone who used the substance in question. If the symptoms are not severe enough to reach the level needed for a diagnosis of delirium, the appropriate diagnosis is a substance-related disorder, either intoxication or withdrawal (see Chapter 9).

Delirium That Arises From Intoxication

When intoxication causes delirium, only a brief time elapses between taking the substance and the emergence of delirium symptoms—minutes to hours. Among older adults, delirium often arises after taking medication on doctor's orders: One study found that up to 20% of older adults are prescribed potentially inappropriate medications (Zhan et al., 2001), which can create unnecessary side effects and interact with other medications to affect cognition and mood.

Most frequently, when the intoxication has worn off, the delirium ends. There are exceptions, however: Some substances, such as PCP, can produce extended delirium. Moreover, some people may have persistent symptoms of delirium even when no longer intoxicated.

Delirium That Arises From Substance Withdrawal

Sometimes, a chronic user of a substance such as alcohol or a hypnotic-sedative can become delirious after stopping the substance use. In fact, delirium tremens (the DTs) arises from withdrawal after alcohol dependence. Depending on the individual and the substance involved, the symptoms of delirium can last from a few hours to 2–4 weeks. The diagnosis of delirium is made only when the cognitive problems associated with withdrawal are significantly more severe than is usual upon withdrawal from the substance, and the symptoms require the attention of medical or mental health professionals.

Delirium Due to a General Medical Condition

Like a fever, delirium can arise for a variety of medical reasons:

- infection,
- dehydration,
- electrolyte imbalance (which can arise from an eating disorder; see Chapter 10),
- stroke,
- brain tumor,
- pneumonia,
- heart attack,
- head trauma, or
- surgery (arising from anesthesia).

Some of these causes, such as dehydration, can be fatal if not treated (Brown & Boyle, 2002).

How do clinicians determine the underlying cause of an individual's delirium? From a physical examination, a consultation with someone who knows the patient and may know something about what led to the symptoms, results of laboratory tests, and a review of the patient's medical history. In some cases, the clinician may need to evaluate the patient a number of times over the course of a day or over several days to determine the specific cause of the delirium (or whether, in fact, the diagnosis of delirium is most appropriate; Kessler, 2006). Delirium can be caused by more than one factor; for example, if someone with alcohol dependence develops an infection and doesn't drink alcohol while the fever is raging, that person's delirium might well arise from both the DTs and the fever.

Gabe Palmer/Corbis

Treating Delirium: Rectify the Cause

Most often, treatment for delirium targets neurological factors—treating the underlying medical condition or substance use that affects the brain and gives rise to the delirium. In most cases, as the medical condition improves or the substance intoxication or withdrawal resolves, the delirium ends. In some cases, though, treatment for the underlying medical problem—for example, administering antibiotics to treat bacterial pneumonia—can take days to affect the delirium; in other cases, as arises when people are close to death, doctors may not be able to treat the underlying cause of the delirium. For temporary relief, the patient may be given antipsychotic medication for the delirious symptoms, usually haloperidol or risperidone (Leentjens & van der Mast, 2005). In fact, studies find that giving haloperidol preventatively to elderly patients about to undergo surgery can decrease the severity and duration of postoperative delirium (Kalisvaart et al., 2005).

Treatment may also target psychological and social factors. Such interventions for people with delirium include (Brown & Boyle, 2002):

- providing hearing aids or eyeglasses to eliminate sensory and perceptual impairments;
- teaching the patient to focus on the here and now, by providing very visible clocks and calendars or other devices and encouraging the patient to use them;
- creating an environment that optimizes stimulation, perhaps by providing adequate lighting and reducing unnecessary noise;
- ensuring that the patient is fed and warm;
- making the environment safe by removing objects with which the patient could harm himself or herself or others; and
- educating the people who interact with the patient (residential staff, friends, and family members) about delirium.

Delirium can arise from a variety of medical problems, including dehydration, or after receiving anesthesia. A percentage of surgery patients—particularly elderly ones—become temporarily delirious in response to anesthesia.

Key Concepts and Facts About Delirium

- According to DSM-IV-TR, delirium is characterized by a disturbance in consciousness and changes in cognitive functioning (particularly in attention). These symptoms develop rapidly and fluctuate over the course of a 24-hour period.
- When delirious, people may not know where they are, who they are, or what day (or year) it is. They may also misinterpret stimuli and experience illusions or have hallucinations. Because they believe that these perceptual alterations are real, patients

continued on next page

may behave accordingly and get hurt—or hurt other people—in the process.

- Delirious people may become either restless and agitated or sluggish and lethargic, or they may rapidly alternate between these two states. Delirium most commonly occurs among the elderly, the terminally ill, and patients who have just had surgery.
- Symptoms of depression, anxiety, dissociation, psychosis, and substance use can appear similar to some symptoms of delirium.
- Delirium can arise from substance intoxication or withdrawal; however, for a diagnosis of delirium related to substance use, the symptoms must be more severe than would normally arise from intoxication produced by, or withdrawal from, the particular substance. Delirium can also arise from a medical condition such as an infection or head trauma or following surgery.

- Treatment for delirium that targets neurological factors often addresses the underlying physical cause, typically through medication. Antipsychotic medication may be given when treatment for the underlying condition isn't possible or will take time to take effect.
- Treatments that target psychological and social factors include correcting sensory impairments, helping patients increase their awareness of the here and now, and educating people who interact with the delirious patient about the symptoms of the disorder.

Making a Diagnosis

- Reread Case 15.2 about Ms. Richardson, and determine whether or not her symptoms meet the criteria for delirium. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Amnestic Disorder

Mrs. B. was not delirious and had not been delirious in the nursing home; she knew who and where she was and her cognitive difficulties—her memory problems—were not transient. In addition to forgetting about planned activities, she'd been forgetting whether she'd taken her medications and forgetting doctor's appointments. The neuropsychologist needed to determine the extent of her memory problems and whether they were worse than those normally associated with aging.

“When questioned about her memory and thinking, she reported that she had “been off track” some before her move and attributed this to [an] “imbalance” resulting from the many stresses that she had experienced in her life. She was vague in describing what she had found stressful, naming the death of her husband (many years before) and the loss or theft of some belongings (how and when unclear). . . .

“Mrs. B. had some reservations at first about being asked more questions about her memory and mood, but as the interview continued, she became more comfortable and worked with good effort. Testing proceeded very slowly because of her tendency to digress, reminiscing about events from her early life or about current circumstances. In general, she was more willing to talk than to participate in structured assessment.”

(LaRue & Watson, 1998, p. 6)

For some older people, the only significant cognitive function that is impaired is memory—in particular, the ability to store new information or to recall or recognize information already stored. Mrs. B.'s memory problems seem to be limited to recent events—such as scheduling appointments—rather than events in her distant past. Either type of memory problem may indicate *amnestic disorder*. In this section we examine amnestic disorder and its neurological causes in more detail.

What Is Amnestic Disorder?

The key characteristic of **amnestic disorder** is impaired memory while other mental processes remain relatively intact. The memory problem may involve difficulty storing new information or recalling previously stored information. DSM-IV-TR allows the clinician to specify whether the memory impairment is *transient* (lasting from a few days to a maximum of 1 month—a type that may arise as a result of seizures), or is *chronic* (lasting for longer than 1 month). The memory problem is

Amnestic disorder

A cognitive disorder characterized by impaired memory while other mental processes remain relatively intact.

Confabulate

To create stories in order to fill in gaps in memory.

most obvious when the person must spontaneously recall information, such as remembering a friend's telephone number. The specific types of memory that are most impaired (such as visual versus verbal and recent versus distant past) depend on the brain areas that have been affected. People with extreme memory problems may need closely supervised care every day. According to DSM-IV-TR, amnesic disorder is characterized only by memory problems and not problems with other cognitive functions. Table 15.4 lists the specific criteria.

Memory problems that arise with amnesic disorder are less likely to affect implicit memory. For instance, a previously acquired ability to type or to drive is often preserved, but someone with amnesic disorder may be unable to explain how to drive or even to remember that he or she *can* drive. Nonetheless, once behind a wheel, the person knows what to do. In spite of being able to perform certain basic tasks that rely on implicit memory, the patient cannot remember factual information—particularly new information—which clearly impairs functioning. As one man with chronic amnesic disorder notes:

I lead a basic lifestyle. I strenuously avoid what I would call “high-risk” situations. That is, situations in which my memory difficulties would leave me lost and disoriented. I don’t even travel to unfamiliar places unless I am accompanied or have a detailed written guide. . . . If I visit the cinema or theater, I must make sure that I won’t have to leave my seat during the screening as I would not be able to find my way back.

I don’t read novels. I will never be able to take a job. Familiarizing myself with the location of the workplace, the nature of the job, the names of my employers and colleagues, the plan of the building, the extent of my responsibilities, etc. would take many weeks. In fact it would not be possible.

(Wilson, 1999, p. 42)

Imagine what it might be like to have serious gaps in your memory: Your wallet isn’t where you thought you left it but is on the kitchen counter instead; at a party, someone who you think is a stranger seems to know a lot about you. To create a sense of coherence in their lives, people with memory problems may **confabulate**—create stories to fill in the blanks in memory. For example, an individual with impaired memory may come to believe that his or her wallet ended up on the kitchen counter because someone else in the family moved it. When a mental health clinician asks such a patient about his or her life or problems, the patient’s report may be a confabulation and hence be inaccurate. One man, Jack, recounts his experience with memory problems, beginning with being asked by a professor to relay a message to a classmate:

I left the room and promptly forgot the message, where to go, the name of the lecturer who’d sent me, and how to return to the room I originally been sent from. I was lost. And I can’t recall what came of the incident . . . many of my recent memories are like this. I start off relatively clear and then fade off as I related the story to myself. And I often find that as faithful to the truth as many of my recollections may be, some are tinged with pure fiction, as if without even realizing it, I am filling in the gaps, the empty times with fabricated notions of the past. . . . But then I am in no position to say whether this is in fact the case. I cannot gauge how accurate any of my memories are.

(Wilson, 1999, p. 41)

Friends or family members may thus be the best source of information about an amnesic patient’s symptoms. Case 15.3 describes a woman with amnesic disorder who did not noticeably confabulate. Additional facts about amnesic disorder are listed in Table 15.5.

Table 15.4 ▶ DSM-IV-TR General Diagnostic Criteria for Amnesic Disorder

- A.** The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.
- B.** The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.
- C.** The memory disturbance does not occur exclusively during the course of a Delirium or a Dementia [discussed later in this chapter] or persists beyond the usual duration of substance delirium or withdrawal.
- D.** There is evidence from the history, physical examination, or laboratory findings that the disturbance is:
 - the direct physiological consequence of a general medical condition (including physical trauma); or,
 - etiologically related to the persisting effects of substance use (e.g., a drug of abuse, a medication).

Source: Adapted from American Psychiatric Association, 2000.

Brand X Photography/Veer

People with amnesic disorder may try to fill the holes in their memories by confabulating—creating stories that make a coherent narrative of their circumstances. For instance, a woman with amnesic disorder might not remember how her underwear came to be in her pocketbook; she might then create a story to explain its presence.

Table 15.5 ▶ Amnestic Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> The prevalence of amnestic disorder is unknown.
Comorbidity
<ul style="list-style-type: none"> Substance-related disorders may contribute to amnestic disorder in some cases.
Onset
<ul style="list-style-type: none"> The age of onset varies, depending on the cause of the memory problems. Symptoms may emerge rapidly or gradually, depending on the cause of the memory problems. Prior to the emergence of the memory problems, the person may be confused or disoriented and have attentional problems, which may lead to a diagnosis of delirium.
Course
<ul style="list-style-type: none"> Depending on the cause of the memory problems, symptoms may last anywhere from a few hours to indefinitely. When the disorder is due to head trauma, symptoms improve the most within the first few months, and may continue to improve for up to 2 years after the trauma. When memory problems begin, the person may confabulate; as the problems persist, the person usually confabulates less or not at all. People may deny that they have memory problems, even when presented with “proof”; they may, in turn, accuse others of manufacturing the “proof.”
Gender Differences
<ul style="list-style-type: none"> Given the lack of research on the prevalence of this disorder, it is unknown whether a sex difference exists.
Source: American Psychiatric Association, 2000.

CASE 15.3 ▶ FROM THE OUTSIDE: Amnestic Disorder

A 55-year-old woman, whom we shall call Ms. A.,

... began to experience progressive difficulties remembering. Her past medical history was unremarkable. There was no family history of neurodegenerative disease. An example of her problem was that she saw the same movie twice within a few days without noticing that she had seen it the first time. Despite her severe memory impairment, she lived independently and continued managing her own shop. She was extremely aware of her predicament and concerned about her future.

Neurological consultation was sought 3 years after the onset of her memory problem. Elementary neurological examination [and tests] were normal ... her only deficit was an amnestic syndrome with amnesia [for recent events. She had a] normal attention span, preserved memory for events that occurred before the onset of her disorder, and no confabulation or false recognition.

Her complaints increased over the following 2 years. Examination 5 years after the onset showed that learning of verbal and nonverbal material was severely impaired. Other cognitive functions were normal. ... At this time she had to give up working because of her memory problem. She remained independent but had to use strategies, to compensate for her disorder. She continued traveling by herself. On one occasion she left her suitcase at one hotel and, not remembering where she had left it, slept at another hotel.

During the following years her memory problems remained unchanged and she was very conscious of her deficit. ... Formal assessment of memory, 13 years after her initial complaint, revealed no additional change in her performance. ... No behavioral change was observed and she remained alert and well groomed. She was fully aware of her predicament and continued caring for herself.

(Didic et al., 1998, pp. 526–527)

What distinguishes amnestic disorder from delirium, which may involve memory problems? With amnestic disorder, the memory problem is the *sole* cognitive impairment—there is no significant change in consciousness or attention or other mental processes—as was the case for Ms. A in Case 15.3. Impaired memory is also the key symptom of dissociative amnesia (see Chapter 8), but with that disorder, the impairment is generally limited to particular types of memories—traumatic or otherwise stressful ones. Moreover, amnestic disorder is diagnosed only when there is strong reason to believe that the memory problems are related to a medical condition or substance use; in contrast, the impaired memory of dissociative amnesia is thought to be caused by psychological trauma. And, although it is normal to have some memory problems with advanced age, a diagnosis of amnestic disorder indicates memory problems that are significantly more severe than those due simply to aging.

Is amnestic disorder an appropriate diagnosis for Mrs. B.'s problems? No; she has other cognitive problems—revealed by her poor performance on the Trail Making Test.

Understanding Amnestic Disorder

Amnestic disorder is caused exclusively by one of two types of neurological factors: substance use or a medical condition. However, the disorder typically has different courses of development in the two cases: When the disorder is caused by chronic substance abuse or exposure to a toxin, memory usually becomes impaired gradually. (One medical condition that gradually leads to amnestic disorder is chronic malnutrition.) In contrast, when amnestic disorder is caused by stroke or trauma to the head, memory becomes impaired rapidly. Let's consider the two types of causes in more detail.

Substance-Induced Persisting Amnestic Disorder

When substance use causes the memory impairment and the amnesia lasts significantly longer than the period of intoxication or withdrawal, the disorder falls under the DSM-IV-TR diagnosis of *substance-induced persisting amnestic disorder*. To make this diagnosis, there must be evidence from the individual's history, a physical examination, or laboratory tests that the impaired memory was caused by substance use, exposure to certain toxins, or the effect of a medication.

Typically, people with this disorder have, or have had, substance dependence. Alcohol is the most common substance that leads to amnestic disorder; in DSM-IV-TR it is referred to as *alcohol-induced persisting amnestic disorder*. Alcohol reduces the absorption of the vitamin *thiamine* from food; thiamine is found in nuts, bread, and some fruits, vegetables, and meats (Hochhalter et al., 2001). Severe thiamine deficiency can lead to significant memory problems, specifically the amnestic disorder called *Korsakoff's syndrome*. Memory symptoms often emerge after age 40, usually abruptly, although subtle memory problems are often evident earlier. Unfortunately, the symptoms are likely to remain stable or diminish only somewhat over time, even with sustained sobriety (Kapur & Graham, 2002; Victor, Adams, & Collins, 1989).

Amnestic disorder can also be caused by environmental toxins such as lead, mercury, and carbon monoxide. In addition, relatively high doses and prolonged intake of a barbiturate (such as Seconal) or a benzodiazepine (such as Valium; see Chapter 9) may cause amnestic disorder. Amnestic disorder caused by such substances has a better prognosis than does that caused by alcohol. Once the individual tapers off the use of the drug, the memory problems usually clear up.

Amnestic Disorder Due to a General Medical Condition

A variety of medical conditions can lead to amnestic disorder (O'Conner & Lafleche, 2006) by damaging brain areas involved in memory: the hippocampus,

Figure 15.2

15.2 ► Brain Areas Affected by Medical Conditions That Cause Amnestic Disorder Medical conditions such as a stroke or a head injury can damage the hippocampus, the mammillary bodies, and the fornix; this damage can lead to amnestic disorder.

the mammillary bodies, and the fornix (see Figure 15.2 for the locations of these brain areas). The clinician determines whether *amnestic disorder due to a medical condition* is the most appropriate diagnosis after reviewing the patient's history—including results of laboratory tests or a physical examination—and determining that the symptoms are not better accounted for by another disorder, such as dissociative disorder or depression.

Treating Amnestic Disorder

No treatment can cure amnestic disorder. However, depending on the specific brain damage and the areas affected, partial or full memory function can sometimes return over time; when memory returns, it usually does so within a couple of years of the onset of the disorder (Wilson, 2004). In most cases, the goal of treatment is *rehabilitation*—helping the patient learn to function as well as possible given the symptoms.

Currently, there are no medications that improve memory in patients with amnestic disorder, although patients may receive medication for comorbid disorders. Rehabilitation of the patient with amnestic disorder typically targets psychological and social factors: (1) helping the patient to develop strategies to compensate for impaired memory, and (2) changing the physical environment so that the patient does not need to rely as much on memory in order to function.

Targeting Psychological Factors: Developing and Implementing New Strategies

Rehabilitation teaches patients techniques and strategies to use to compensate for their memory problems (Wilson, 2004), particularly ways of organizing information so that it can later be retrieved from memory more readily. One such strategy is the use of *mnemonics*, which may help people to remember simple information, such as where the car is parked at the mall. For example, someone whose visual memory is not significantly impaired might imagine the location of the car in the parking lot, which will help him or her retain this information. Another strategy

is to write down any information that must be retrieved later, such as by making a note about where in the parking lot the car is parked.

Depending on the patient's abilities and inclinations, he or she may use a variety of memory aids: diaries, notebooks, alarms, calendars, or hand-held electronic personal digital assistants (PDAs). A PDA-type device can be a very effective memory aid because an alarm can be set to go off at the appropriate time, and the device can display a text message telling the patient what he or she needs to do at that moment ("Take red pill now" or "Go to Dr. Gabi's office at 23 Main Street") (Kapur, Glisky & Wilson, 2004). In contrast to memory aids that require the patient to remember to use the tools (as in remembering to look at written notes), PDAs do not require the patient to remember as much information. Table 15.6 lists various memory aids.

If a patient has not previously used such memory aids, however, he or she must be taught how to use them, which can create a paradox: Even after learning how to use a memory aid, the patient must later remember how to use it and then remember to use it in the appropriate situation. Depending on the specific nature of the memory problems, though, many patients can learn new strategies and use them. To ensure that a patient has learned a technique or strategy, the clinician should do the following (Wilson, 2004):

- Explain the to-be-learned information as simply as possible.
- Ask the patient to remember only one piece of information or one procedure at a time. For instance, a patient who had never used a PDA before, such as Ms. A. in Case 15.3, should first learn how to use the device to access stored information (such as a grocery list) before learning how to enter new information into it.
- Make sure that the patient understands the information—if the information is verbal, he or she should paraphrase the information and repeat it back to the clinician. For instance, after the clinician explained to Ms. A. how to access information on the PDA, such as the grocery list, Ms. A. should paraphrase those instructions.
- Link the new information to something the patient already knows. For instance, the clinician could program the PDA so that pressing and holding the G key accesses the grocery list and pressing and holding the M key accesses a medication schedule.
- Have the patient rehearse and practice the learned information frequently. For example, Ms. A. should repeatedly access the grocery list while with the clinician. Once she has mastered this step, she can proceed to learn how to add information to the grocery list.
- Make sure that the patient is actively thinking about the information, not simply parroting it.

Patients are more likely to remember their own actions than the corrections of errors they make. Thus, mental health professionals may use **errorless learning techniques** to teach patients new information (Kessels & de Haan, 2003): Patients are explicitly guided in learning a new skill rather than being allowed to figure it out through trial and error. For instance, if using errorless learning to teach Ms. A. how to enter a grocery list into a PDA, the clinician would discourage guessing and give as much information as Ms. A. needed to enter the list correctly the first time. If she didn't know what to do at a given step, the clinician would show her or provide help ranging from very specific guidance ("Now press the green button") to hints or prompts ("What do you do first to add an item?"), depending on her ability to take the next step correctly.

Electronic devices can serve as memory aids for patients with amnesic disorder. They can be programmed so that an alarm goes off at a particular time, when the screen displays a message about some action the patient should take.

Mint Photography

Table 15.6 ▶ Memory Aids for People With Memory Problems

- Alarm clock for waking up
- Clock or watch to tell the date as well as the time
- Watch with a timer (for elapsed time)
- An appointment diary
- A journal (to write about and later read about events or experiences that otherwise would be forgotten)
- A notebook for writing notes to self
- Lists of things to do or buy, such as groceries
- Labels on cabinets and drawers
- Sticky notes with reminders about chores to be done
- A tape recorder for creating auditory notes to self
- Asking other people to provide reminders
- A PDA

Source: Adapted from Wilson, 1999, p. 35, Table 3.4.

Errorless learning techniques

Techniques by which patients are explicitly guided in learning a new skill rather than being allowed to figure it out through trial and error.

This man has significant memory problems. The notes on his dresser drawers label the type of items in each drawer. Such modifications to his environment can reduce the impact of his memory problems, and make his experience getting dressed each morning less confusing or frustrating.

One way to reduce the cognitive load of someone with amnesic disorder is to enlist others to structure the patient's environment so that memory is less important. For instance, family members can place labels on the outside of cupboard doors and room doors at home or at a residential facility; each label identifies what is on the other side of the door (for example, "dishes," "kitchen," "Sally Johnson's room"). In some rehabilitation centers, the doors to bathrooms are painted a distinctive color, and arrows on the walls or floors show the direction to a bathroom, so patients don't need to rely as much on memory to get around the facility (Wilson, 2004).

The challenge with memory aids is to overcome the patient's difficulty in remembering to use the strategies and devices in real-life settings. To facilitate such generalization, the clinician may teach family members or others how to use the strategies and devices and how to help the patient use them in his or her home environment.

Targeting Social Factors: Organizing the Environment

One way to reduce the cognitive load of someone with amnesic disorder is to enlist others to structure the patient's environment so that memory is less important. For instance, family members can place labels on the outside of cupboard doors and room doors at home or at a residential facility; each label identifies what is on the other side of the door (for example, "dishes," "kitchen," "Sally Johnson's room"). In some rehabilitation centers, the doors to bathrooms are painted a distinctive color, and arrows on the walls or floors show the direction to a bathroom, so patients don't need to rely as much on memory to get around the facility (Wilson, 2004).

Key Concepts and Facts About Amnesic Disorder

- Amnesic disorder is characterized by significant deficits solely in memory—other cognitive functions remain relatively intact. People with amnesic disorder may confabulate to fill in memory gaps, and they may not be able to report their history accurately during a clinical interview. Amnesic disorder can be transient or chronic.
- When trying to determine whether amnesic disorder is the most appropriate diagnosis for a patient with memory problems, the clinician must rule out other disorders that can give rise to memory problems, including delirium and dissociative amnesia; the clinician must also determine that the memory impairment is more severe than would be expected from normal aging.
- Amnesic disorder is caused exclusively by two types of neurological factors: (1) substance use (leading to substance-induced persisting amnesia, which most frequently occurs with severe and chronic alcohol dependence), or (2) a medical condition, such as stroke, head trauma, or the effects of surgery.
- Rehabilitation focuses on helping amnesic patients learn to use organizational strategies (such as mnemonics or writing down information) and memory aids (such as diaries and PDAs). A patient's environment can be structured in order to minimize the amount of information that needs to be remembered to function in daily life—for example, by putting identifying labels on doors.

Making a Diagnosis

- Reread Case 15.3 about Ms. A., and determine whether or not her symptoms meet the criteria for amnesic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Dementia

Mrs. B. seemed to have some memory problems, but memory was not the only aspect of her cognitive functioning that had declined. During neuropsychological testing, "the principal areas of difficulty on [certain] tests were in mental control, as evidenced by tangential and repetitive speech; psychomotor slowing [in this case, slow movements based on mental processes, not reflexes]; and reduced flexibility in thought and action" (LaRue & Watson, p. 9). Some of these difficulties are characteristic of *dementia*. Could Mrs. B. have dementia?

In this section we focus on dementia: what it is, what neurological factors give rise to it, and what treatments are available for it.

What Is Dementia?

Dementia is the general term for a set of cognitive disorders that is characterized by deficits in learning new information or recalling information already learned *plus* at least one of the following types of impaired cognition (American Psychiatric Association, 2000):

- **Aphasia.** In dementia, aphasia often appears as overuse of the words *thing* and *it* because of difficulty remembering the correct specific words.
- **Apraxia.** Problems with executing motor tasks (even though there isn't anything wrong with the appropriate muscles, limbs, or nerves) can lead to problems dressing and eating, at which point self-care becomes impossible.
- **Agnosia.** People with dementia may not recognize friends, family members, or even the face in the mirror.
- **Executive function problems.** These problems lead to difficulties in planning, initiating, organizing, abstracting, and sequencing or even in recognizing that one has memory problems. (These problems arise primarily in dementia that affects the frontal lobes.) These deficits can make it impossible to meet the demands of daily life. Mrs. B. evidenced some difficulties in tasks that required executive functions.

We discussed aphasia, apraxia, and agnosia earlier, in the context of effects of brain damage on cognition. Unlike the effects of a stroke or a head injury, however, dementia is not caused by an isolated incident. Rather, it arises over a period of time, as brain functioning degrades; symptoms of dementia often change over time, typically becoming worse, but sometimes remaining static or even reversing course.

To be diagnosed as having dementia, a person must have cognitive deficits severe enough to impair daily functioning, and these deficits must contrast with a prior, more adaptive level of functioning. Table 15.7 summarizes the DSM-IV-TR diagnostic criteria for dementia.

Mild symptoms of dementia may go unnoticed in people whose cognitive functioning started out at a very high level. Such a patient may detect his or her compromised ability to function, but neuropsychological testing is likely to show that the patient's abilities are within the normal range for his or her age—and so the early signs of dementia would go undiagnosed (Harvey, 2005a). Most people with dementia are over 65 years of age when symptoms emerge, and in these cases, DSM-IV-TR specifies that the disorder has *late onset*. When symptoms begin before age 65, the disorder is said to have *early onset*. Early onset, particularly before age 50, is rare and is usually hereditary (Ikeuchi et al., 2008).

Depending on the specific mental processes that are impaired, a patient with dementia may

- behave inappropriately (for instance, tell unsuitable jokes or be overly familiar with strangers);

Dementia

A set of cognitive disorders characterized by deficits in learning new information or recalling information already learned *plus* at least one other type of cognitive impairment.

Table 15.7 ▶ DSM-IV-TR General Diagnostic Criteria for Dementia

- | |

- misperceive reality (for instance, think that a caretaker is an intruder); or
- wander away while trying to get “home” (a place where he or she lived previously).

Impaired cognitive functioning can lead many patients to feel easily overwhelmed or confused and become agitated. The agitation or confusion may cause a patient to become violent, which can make it difficult or potentially dangerous for the patient to remain living at home with family members—and hence the patients may be moved to a residential care facility.

The most common cause of dementia is **Alzheimer’s disease** (also called “dementia of the Alzheimer’s type,” or simply Alzheimer’s), in which the afflicted individual initially has problems with both memory and executive function (such as difficulty with abstract thinking and impaired judgment). As the disease advances, memory problems worsen, and attention and language problems emerge, and spatial abilities may deteriorate; the patient may even develop psychotic symptoms, such as hallucinations and delusions (particularly delusions of persecution). In the final stage, the patient’s memory loss is complete—he or she doesn’t recognize family members and friends, can’t communicate, and is completely dependent on others for care. In Case 15.4, Diana Friel McGowin describes her experience with Alzheimer’s disease; additional facts about dementia are provided in Table 15.8.

Table 15.8 ▶ Dementia Facts at a Glance

Prevalence

- About 5 million older Americans are estimated to have dementia (Alzheimer’s Association, 2007).
- Among those between 65 and 69 years of age, 1–2% are diagnosed with dementia; the prevalence doubles with every additional 4 years of age.
- Dementia occurs most frequently in those over 85 years old; 16–30% of people in this age group are diagnosed with dementia (Knopman, Boeve, & Petersen, 2003; Ritchie & Lovestone, 2002).

Comorbidity

- Depression (Kales et al., 2005; Snow et al., 2005) and psychotic symptoms such as hallucinations and delusions (Tractenberg et al., 2003) commonly co-occur with dementia.

Onset

- Onset usually occurs late in life.
- Cognitive deterioration can be rapid or gradual, depending on the cause of the dementia.
- Impaired learning and recall are early signs of some types of dementia.

Course

- People with dementia may be unable to perform complex tasks in new situations but still be able to perform simple ones in familiar surroundings.
- Some types of dementia, such as that caused by Alzheimer’s disease, get progressively worse (these types are referred to as *progressive dementias*); other types of dementia, such as that caused by HIV infection, can get better with treatment of the underlying cause. Still other types remain relatively unchanging.

Gender Differences

- Dementia is slightly more common in males than in females.

Cultural Differences

- Some cultures and ethnic groups—such as African Americans, Asian Americans, and Hispanic Americans—may be more tolerant of impaired memory and other cognitive dysfunctions that affect the elderly, in some cases, viewing these changes as a normal part of aging. Family members thus may wait longer before seeking medical assistance for an older person with dementia (Cox, 2007).

Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

Alzheimer’s disease

A medical condition in which the afflicted individual initially has problems with both memory and executive function and which leads to progressive dementia.

CASE 15.4 ► FROM THE INSIDE: Dementia

Diana Friel McGowin was 45 years old when she became aware of memory problems. She got lost on the way home because no landmarks looked familiar; she was unable to remember her address or to recognize her cousin. After neuropsychological and neuroimaging tests, she was diagnosed with early-onset Alzheimer's disease (because the disorder emerged before age 65). In her memoir about the progressive nature of this disease, *Living in the Labyrinth* (1993), McGowin describes sharing with her neurologist some of the symptoms she was having:

I showed him the burns on my wrists and arms sustained because I forgot to protect myself when inserting or removing food from the oven. I told him of becoming lost in the neighborhood grocery store where I had shopped for over twenty years. I showed him my scribbled notes and sketched maps of how to travel to the bank, the post office, the grocery, and work. (p. 41)

She describes other memory problems as the disease progressed:

I sometimes lost my thread of thought in mid-sentence. Memories of childhood and long ago events were quite clear, yet I could not remember if I ate that day. On more than one occasion when my grandchildren were visiting, I forgot they were present and left them to their own devices. Moreover, on occasions when I had picked them up to come play at my house, the small children had to direct me home. (pp. 64–65)

Further into her memoir, she notes:

As my grip upon the present slips, more and more comfort is found within my memories of the past. Childhood nostalgia is so keen I can actually smell the aroma of the small town library where I spent so many childhood hours. (p. 109)

Painfully lonely, I still contrarily, deliberately, sit alone in my home. The radio and TV are silent. I am suspended. Somewhere there is that ever-present reminder list of what I am supposed to do today. But I cannot find it. (p. 112)

In the early phases of a progressive dementia, when the person has relatively little decline in executive function, he or she may become so depressed about the diagnosis and its prognosis that he or she attempts suicide. Diana McGowin, in Case 15.4, became acutely aware of her symptoms during the early phase of the disease and worked hard to try to compensate by making maps and lists.

Distinguishing Between Dementia and Other Psychological Disorders

The symptoms of dementia—impaired memory and other cognitive dysfunctions—also occur with other disorders and can resemble symptoms of other disorders, which sometimes makes an accurate diagnosis challenging. The following disorders have symptoms that may seem similar to those of dementia:

- *Mental retardation.* However, mental retardation does not primarily involve memory problems; moreover, mental retardation is diagnosed in young people. Clinicians must keep in mind that people whose intellectual functioning in early and middle adulthood was in the low average range or below (an IQ of 85 or less) may have difficulty functioning as the normal changes with aging are superimposed on the lower baseline level of cognitive abilities. Such people may technically meet the criteria for dementia in older adulthood (Heaton, Grant, & Matthews, 1991).
- *Schizophrenia.* Although both dementia and schizophrenia often involve hallucinations and delusions, schizophrenia is usually diagnosed earlier in adulthood. Moreover, schizophrenia has a standard set of positive and negative symptoms

(Harvey, 2005b; see Chapter 12). Although some people develop schizophrenia later in life (which can make it difficult to distinguish it from dementia by the age of onset), such later-onset schizophrenia often progresses rapidly from the prodromal phase—when symptoms are just beginning to emerge—to a full psychotic episode, whereas psychotic symptoms are likely to emerge more gradually with dementia (Harvey, 2005c).

- **Depression.** A clinician may find it particularly difficult to distinguish between depression and dementia in elderly patients—both disorders can involve memory problems, poor concentration, and other cognitive dysfunctions. The timing of the onset of symptoms can help distinguish the two disorders: Patients with depression often have relatively normal cognitive functioning before becoming depressed and then rapidly decline. In contrast, those with dementia may have a slower cognitive decline.
- **Delirium.** With some patients, the particular symptoms can make it difficult for mental health clinicians to determine whether delirium, dementia, or both are present (see Table 15.9). Friends or family members may be called on to provide a more accurate history of a patient's symptoms than the patient can provide.
- **Amnestic disorder.** Both amnestic disorder and dementia involve memory problems. However, a diagnosis of dementia requires that additional cognitive deficits be present.
- **Normal aging.** It is normal for adults to experience some decline in cognitive functioning with increasing age; to be considered as dementia, an elderly person's cognitive problems must be significantly worse than would be normally expected and must be caused by a medical condition or related to substance use.

Table 15.9 ▶ Symptoms Unique and Common to Delirium and Dementia

Unique to Delirium	Unique to Dementia	Common to Both Delirium and Dementia
<ul style="list-style-type: none"> • Delirium has a rapid onset. • Symptoms (including changes in consciousness) fluctuate within a 24-hour period. • Hallucinations—frequently visual—are present. • Symptoms often gradually improve. • The person is not alert and focused. 	<ul style="list-style-type: none"> • Dementia has a gradual onset. • Symptoms typically do not fluctuate within a 24-hour period. • Hallucinations are often absent. • Symptoms rarely improve. • The person is consistently alert. 	<ul style="list-style-type: none"> • Memory problems • Problems with other types of cognitive functioning

Understanding Dementia

Dementia is caused by a variety of neurological factors, and according to DSM-IV-TR, each of these factors corresponds to a specific dementia diagnosis. Let's review the most common types of dementia: dementia of the Alzheimer's type, vascular dementia, and dementia due to other general medical conditions.

Dementia of the Alzheimer's Type

Almost three quarters of dementia cases are caused by Alzheimer's disease (Plassman et al., 2007). There is no routine lab test for diagnosing this disease at present, and so this type of dementia is diagnosed by excluding or ruling out other possible causes.

The Progression of Alzheimer's Disease

The onset of Alzheimer's disease is gradual, with symptoms becoming more severe over time. Often, the early signs of dementia of the Alzheimer's type involve difficulty remembering recent events or newly learned information. In fact, in the early stages of Alzheimer's, the memory problems may be diagnosed as amnesic disorder (Petersen & O'Brien, 2006); it is only as the disease progresses that other cognitive dysfunctions emerge.

Within a few years of onset, symptoms may include aphasia, apraxia, and agnosia. Spatial abilities may deteriorate markedly. Patients may also become irritable and their personality may change, and such changes may become more pronounced as cognitive functioning declines. In the final stage of the disease, motor problems arise, creating difficulties with walking, talking, and self-care. Generally, these patients die about 8–10 years after the first symptoms emerge. Table 15.10 describes normal functioning with aging and the five stages of the disorder's progression in more detail.

In some cases, people with dementia also exhibit behavioral disturbances, such as agitation or wandering about, which arise because of the cognitive deficits—they get lost or, like Ms. McGowin, they can't remember their destination. DSM-IV-TR

Table 15.10 ► Normal Functioning and the Five Stages of Dementia of the Alzheimer's Type

Level of Cognitive Impairment	Clinical Phase	Clinical Characteristics	Diagnosis
1 = No Cognitive Decline	Normal	No subjective complaints of memory deficit. No memory deficit evident on clinical interview.	Normal
2 = Very Mild Cognitive Decline	Forgetfulness	Subjective complaints of memory deficits. No objective deficits in employment or social situations. Appropriate concern with respect to symptomatology.	Normal aged
3 = Mild Cognitive Decline	Early confusional	Earliest clear-cut deficits. Decreased performance in demanding employment and social settings. Objective evidence of memory deficit obtained only with an intensive interview. Mild to moderate anxiety accompanies symptoms. When introduced to new people, has increased difficulty remembering their names. Word-finding problems noticeable to other people. Loses objects.	Compatible with incipient Alzheimer's disease
4 = Moderate Cognitive Decline	Late confusional	Clear-cut deficit on careful clinical interview. Inability to perform complex tasks. Although patient has significant memory problems, denies them or blames others for problems. Flattening of affect and withdrawal from challenging situations occur. Inability to perform complex tasks such as paying bills.	Mild Alzheimer's disease
5 = Moderately Severe Cognitive Decline	Early dementia	Patients can no longer survive without some assistance. Patients are unable during interview to recall a major relevant aspect of their current lives. Persons at this stage retain knowledge of many major facts regarding themselves and others. They invariably know their own names and generally know their spouses and children's names. They require no assistance with toileting or eating, but may have some difficulty choosing the proper clothing to wear.	Moderate Alzheimer's disease
6 = Severe Cognitive Decline	Middle dementia	May occasionally forget the name of the spouse upon whom they are entirely dependent for survival. Will be largely unaware of all recent events and experiences in their lives. Will require some assistance with activities of daily living. Personality and emotional changes occur, such as suspiciousness; may develop psychotic symptoms, wander, and become lost.	Moderately severe Alzheimer's disease
7 = Very Severe Cognitive Decline	Late dementia	All verbal abilities are lost. Frequently there is no speech at all—only grunting. Incontinent of urine; requires assistance toileting and feeding. Loses basic psychomotor skills (e.g., ability to walk).	Severe Alzheimer's disease

Source: Adapted from Reisberg et al., 1982, Table 12.1.

Table 15.11 ▶ Prevalence of Dementia of the Alzheimer's Type From Age 65 On

Age (in years)	Prevalence Among Males	Prevalence Among Females
65	0.6%	0.8%
85	11%	14%
90	21%	25%
95	36%	41%

As people age beyond 65 years old, they are increasingly likely to develop Alzheimer's disease. About half the cases in each age group have moderate to severe cognitive impairment (American Psychiatric Association, 2000).

allows clinicians to note whether the individual's dementia occurs *with behavioral disturbance* or *without behavioral disturbance*. One woman describes her husband's recent behavioral disturbances:

My husband used to be such an easy-going, calm person. Now, he suddenly lashes out at me and uses awful language. Last week, he got angry when our daughter and her family came over and we sat down to eat. I never know when it's going to happen. He's changed so much—it scares me sometimes.

(National Institute on Aging, 2003, p. 47)

People with Alzheimer's who exhibit behavioral disturbances are more likely to have greater declines in cognitive functioning and to need institutional care sooner than patients whose behavior causes less concern (Scarmeas et al., 2007). As noted in Table 15.11, slightly more females than males develop this form of dementia, and it accounts for progressively more cases of dementia in older age groups.

Brain Abnormalities Associated With Alzheimer's Disease: Neurofibrillary Tangles and Amyloid Plaques

Two brain abnormalities are associated with Alzheimer's disease: *neurofibrillary tangles* and *amyloid plaques*. In the following we consider each of these abnormalities.

The internal support structure of a neuron includes microtubules, which are tiny hollow tubes that create tracks from the cell body to the end of the axon; nutrients are distributed within the cell via these microtubules. A protein, called *tau*, helps stabilize the structure of these tracks (see Figure 15.3). With Alzheimer's disease, the tau proteins become twisted together in what are called **neurofibrillary tangles**, and these proteins no longer hold together the microtubules—which thereby disrupts the neuron's distribution system for nutrients. In addition, the collapse of this support structure prevents normal communication with other neurons. This process may also contribute to the death of neurons. In fact, people with Alzheimer's have smaller brains than normal (Henneman et al., 2009).

The brains of people with Alzheimer's disease are abnormal in another way—they have **amyloid plaques**, which are fragments of proteins (one type of which

Figure 15.3

15.3 ▶ Neurofibrillary Tangles in Alzheimer's Disease

Tau proteins stabilize the structure of a neuron from the cell body through the end of the axon. With Alzheimer's disease, these proteins become entangled, destroying the structure of the neuron and disrupting its communication with other neurons.

Source: National Institute of Aging.

Neurofibrillary tangles

The mass created by tau proteins that become twisted together and destroy the microtubules, leaving the neuron without a distribution system for nutrients.

Galerie Beckel-Odille-Boicos

Galerie Beckel-Odille-Boicos

is called *amyloid*) that accumulate on the outer surfaces of neurons, particularly neurons in the hippocampus (the brain area predominately involved in storing new information in memory).

Researchers have not yet determined whether the neurofibrillary tangles and plaques *cause* Alzheimer's disease or are a by-product of some other process that causes the disease (National Institute of Aging, 2003). However, neurofibrillary tangles and amyloid plaques are generally discovered during autopsies, and PET scanning that used a particular chemical marker has been able to detect the amyloid plaques and neurofibrillary tangles that distinguish Alzheimer's disease from other causes of memory problems in living patients (Small et al., 2006). Additional studies have corroborated the potential of such PET scanning to detect Alzheimer's disease (Ikonomovic et al., 2008). And other experimental biomedical tests have been designed to identify biological markers that distinguish patients with Alzheimer's. For example, one test compares blood samples and cerebrospinal fluid from patients with Alzheimer's disease, patients with dementia due to Parkinson's disease (which we will discuss shortly), and healthy control participants (Neale, 2008). Preliminary studies using this test have been successful in distinguishing among the types of participants.

Genetics

People who have a specific version of one gene, *apo E*, are more susceptible to late-onset Alzheimer's disease than those who don't have this particular gene. However, someone can have this version of the *apo E* gene and not develop Alzheimer's; conversely, someone can develop Alzheimer's and not have this version of the gene.

In contrast, early-onset Alzheimer's is caused by mutation of one of three other genes, and two of these mutations lead to Alzheimer's disease in 100% of cases. However, the third type of mutation, a rare form called *presenilin 2*, does not always cause the disease (Bird et al., 1996; Williamson-Catania, 2007), which suggests that other neurological factors and/or psychosocial factors play a role.

Vascular Dementia

Vascular refers to blood vessels, and *vascular diseases* refer to problems with blood vessels, such as high blood pressure or high cholesterol. Vascular disease can reduce or block blood supply to the brain, which in turn can cause **vascular dementia**. Blood vessels are involved in dementia in two possible ways: (1) plaque

Artist William Utermohlen learned in 1995 that he had Alzheimer's disease—which causes a type of progressive dementia. He responded to the news by painting self-portraits. Alzheimer's can specifically affect brain areas involved in spatial abilities, which are crucial for painting. As his dementia progressed, Utermohlen's images became less distinct and more abstract; these three portraits were done in (left to right) 1998, 1999, and 2000. Although he recognized that his paintings weren't what he wanted, he said that he “could not figure out how to correct them” (Grady, 2006).

Amyloid plaques

Fragments of protein that accumulate on the outside surfaces of neurons, particularly neurons in the hippocampus.

Vascular dementia

A type of dementia caused by reduced or blocked blood supply to the brain, which arises from plaque buildup or blood clots.

A buildup of plaque in the arteries can lead to decreased blood supply to the brain, which can cause vascular dementia.

builds up on artery walls, making the arteries narrower, which then diminishes blood flow to the brain, or (2) bits of clotted blood block the inside of arteries, which then prevents blood from reaching the brain—which, as we noted earlier, produces a stroke. Such clots can cause a series of small strokes (sometimes referred to as *transient ischemic attacks* or *ministrokes*) in which blood supply to parts of the brain is temporarily blocked, leading to transient impaired cognition or consciousness. When multiple ministrokes occur over time, dementia can arise as brain areas involved in cognitive functioning become impaired. This form of dementia can have a gradual onset. In contrast, a single, large stroke inflicts more brain damage than a series of ministrokes; in such cases, vascular dementia has an abrupt onset.

A clinician makes the diagnosis of vascular dementia based on the patient's laboratory test results and on abnormal reflexes or responses during a neurological examination (for instance, weakness in a limb or problems in walking). Symptoms of vascular dementia can wax and wane

over a given 24-hour period, but even the patient's highest level of functioning is lower than it was before dementia set in (Puente, 2003). In addition, neuroimaging may reveal lesions in particular brain areas. People with vascular dementia may also have Alzheimer's disease, particularly if they are very old (Kalaria & Ballard, 1999). Vascular dementia is more common in men than women.

The course of the disorder is variable, depending on the specific brain areas affected; when symptoms become more severe, they worsen in a stepwise fashion, with more deficits apparent after each instance of reduced blood supply to the brain. Aggressive treatment of the underlying vascular disease (typically via medication) may prevent additional strokes or reduced blood flow to brain areas.

Dementia Due to Other General Medical Conditions

Dementia can also be caused by a variety of other medical conditions, including Parkinson's disease, late-stage HIV infection, and Huntington's disease. With these and certain other medical conditions, the onset can be gradual or sudden, the course can range from acute to chronic, and the patient may also develop behavioral disturbances. Let's look at some of the general medical conditions that can cause dementia.

Dementia Due to Parkinson's Disease

Parkinson's disease is characterized by a slow, progressive loss of motor function; typical symptoms are trembling hands, a shuffling walk, and muscular rigidity. About 1 million Americans have Parkinson's disease, and around 50% of people with Parkinson's disease develop dementia due to this disease. Those who develop dementia are usually older (age of onset is about 65 years old) or are in a more advanced stage of the disease (Papapetropoulos et al., 2005). The dementia generally involves problems in memory and executive functions. Comorbid depression can cause even more cognitive dysfunctions.

Parkinson's disease causes damage to dopamine-releasing neurons in an area of the brain known as the *substantia nigra*. As a consequence, the brains of these patients do not have normal amounts of this neurotransmitter, which is critically involved in motor functions as well as executive functions. Parkinson's disease is thought to arise from a combination of genetic inheritance and other neurological factors, such as brain damage caused by exposure to toxins (for example, pesticides).

Dementia Due to Lewy Bodies

Another type of progressive dementia is **dementia due to Lewy bodies**. *Lewy bodies* consist of a type of protein that, in some people, builds up inside neurons that produce dopamine and acetylcholine and can eventually cause the neurons to die. The neurons most often affected are involved in memory and motor control (but neurons associated with other functions can also be affected).

Dementia due to Lewy bodies

A type of progressive dementia caused by a type of protein (referred to as Lewy bodies) that builds up inside some types of neurons and can eventually cause them to die.

The early stage of dementia due to Lewy bodies is marked by visual hallucinations, fluctuations in attention and consciousness throughout the day (with long periods of time spent staring into space or being drowsy), and a stiffness of movement that is similar to that of people with Parkinson's disease (rigid muscles, tremors, slowed movements, and a shuffling style of walking). Clinicians may have difficulty distinguishing this form of dementia from Alzheimer's, and about 20% of people who were diagnosed with Alzheimer's were found also to have abnormal Lewy bodies (which were discovered on autopsy; Rabin et al., 2006). The main features that are present in dementia due to Lewy bodies but tend not to be as marked in dementia due to Alzheimer's disease are:

- (1) the presence of (visual) hallucinations early in the course of the disorder,
- (2) a tendency to retain the ability to name objects,
- (3) very poor visuospatial ability, and
- (4) impaired executive functions (Kaufer, 2002; Knopman, Boeve, & Petersen, 2003; Walker & Stevens, 2002).

Like patients with Alzheimer's disease, patients with dementia due to Lewy bodies progressively deteriorate until death, which on average occurs about 8–10 years after diagnosis.

Dementia Due to HIV Disease

The human immunodeficiency virus (HIV) can cause widespread destruction of white matter and of subcortical brain areas; this damage gives rise to dementia. The symptoms of this form of dementia include impaired memory, concentration, and problem solving, as well as cognitive slowing. Moreover, patients may exhibit signs of apathy and social withdrawal or delirium, delusions, or hallucinations. They may develop tremors or repetitive movements or have balance problems (McArthur et al., 2003; Price, 2003; Shor-Posner et al., 2000). Antiretroviral medications that treat HIV infection slow and in some cases may actually reverse the brain damage, improving cognitive functioning (Sacktor et al., 2006).

Dementia Due to Huntington's Disease

Huntington's disease is a progressive disease that kills neurons and affects cognition, emotion, and motor functions; it leads to dementia and eventually results in death. Early symptoms of Huntington's include bipolar-like mood swings between mania and depression, irritability, and psychotic symptoms (e.g., hallucinations or delusions). Motor symptoms include slow or restless movements, and the symptoms of dementia include memory problems (which become severe as the disease progresses), executive dysfunction, and poor judgment.

Between 5 and 7 people per 100,000 develop Huntington's disease (Folstein, 1989). Men and women are equally affected; the disease is usually diagnosed when patients are in their late 30s or early 40s, but the age of onset can range from 4 years old to 85 years old.

Huntington's disease is inherited and is based on a single gene. If a parent has Huntington's disease, his or her children each have a 50% chance of developing it. Genetic testing can assess whether the gene is present. However, even if the gene is present, the disorder does not always develop.

Dementia Due to Head Trauma

Just as head trauma can cause amnesic disorder, it can also cause dementia. The precise deficits and their severity depend on which brain areas are affected and to what degree. The individual with this form of dementia may also exhibit behavioral disturbances, such as agitation or anxiety. Such a patient may have amnesia for events during and after the trauma, as well as other persistent memory problems. In addition, he or she may exhibit sensory or motor problems and even personality changes (becoming increasingly aggressive or apathetic or suffering severe mood swings) (American Psychiatric Association, 2000).

Huntington's disease

A progressive disease that kills neurons and affects cognition, emotion, and motor functions; it leads to dementia and eventually results in death.

This form of dementia is most common among young males, who are more likely to engage in risk-taking behaviors (including reckless drinking). In some cases, the dementia is caused by a single trauma to the head (such as a car accident) and is unlikely to get worse; when the dementia is caused by multiple traumas (as occurs with boxers) it may become worse over time (American Psychiatric Association, 2000).

Substance-Induced Persisting Dementia

When the cognitive deficits of dementia are caused by substance use but persist beyond the period of intoxication or withdrawal, the clinician makes the diagnosis of *substance-induced persisting dementia*. A patient who receives this diagnosis usually has a long history of substance dependence, and symptoms rarely occur in patients younger than 20 years old. The onset is slow, as is the progression of deficits—the first symptoms arise while the person has substance dependence. The deficits are often not reversible and may even get worse when the substance use is discontinued, although there are exceptions (American Psychiatric Association, 2000).

As we've noted, dementia may be caused by any number of medical illnesses or conditions, and these causes are not mutually exclusive; in a given individual, dementia may have more than one cause. For example, someone may have both vascular dementia *and* Alzheimer's disease. When this occurs, the clinician diagnoses each type (cause) separately. Table 15.12 summarizes key facts about the different types of dementia.

Table 15.12 ▶ Key Facts About Different Types of Dementia

Dementia due to . . .	Approximate percentage of dementia cases	Prognosis/Course	Onset	Gender difference
Alzheimer's Disease	70%	Poor	Gradual, often after age 65; early onset is rare.	Slightly more common among females than males
Vascular Disease	15% (often comorbid with Alzheimer's type)	Cognitive loss may remain stable or worsen in a stepwise fashion.	Abrupt; earlier age of onset than Alzheimer's	More common among men
Lewy Bodies	15% (can be comorbid with Alzheimer's type)	Poor	Gradual; age of onset is between 50 and 85.	Slightly more common among men than women
HIV Infection	Less than 10%	Poor unless treated with antiretroviral medication	Gradual; depends on age at which HIV infection is acquired	Estimates of sex ratios vary, depending in part on the sex difference in HIV prevalence and the availability of antiretroviral treatment at the time a study is undertaken.
Parkinson's Disease	Less than 10%; often comorbid with Alzheimer's type and/or vascular dementia; about 50% of patients with Parkinson's disease develop dementia.	Poor	Gradual; typical age of onset is in the 70s.	More men than women develop Parkinson's disease, and so men are more likely to develop this type of dementia.
Huntington's Disease	Less than 10%	Poor	Gradual; onset usually occurs in the 40s or 50s.	No sex difference
Head Trauma	Unknown	Depends upon the specific nature of the trauma	Usually abrupt, after the head injury	Unknown, but most common among young males
Substance-Induced	Unknown	Variable, depends on the specific substance and deficits	Gradual; in the 30s and beyond	Unknown

Note: Most cases of dementia are caused by Alzheimer's disease. However, dementia in a given individual can arise from more than one cause, and the percentages in the second column reflect these comorbidities; for this reason, the numbers add up to more than 100%.

Treating Dementia

With most types of dementia, such as the Alzheimer's type and vascular dementia, no treatments can return cognitive functioning to normal. There is one exception to this general situation: antiretroviral medications sometimes can significantly reduce symptoms of dementia caused by HIV infection. However, as with amnesic disorder, for most other types of dementia, treatment largely consists of rehabilitation. Given the high proportion of dementia that is caused by Alzheimer's disease (see Table 15.12), in the following sections we focus on treatment for that type of dementia, unless otherwise noted.

Targeting Neurological Factors

Medications have been developed to delay the progression of cognitive difficulties in people with Alzheimer's disease. One class of drugs, *cholinesterase inhibitors*, such as *galantamine* (Razadyne) or *donepezil* (Aricept), is used for mild to moderate cognitive symptoms; these medications increase levels of acetylcholine (American Association of Geriatric Psychiatry, 2006; Lanctôt et al., 2003; Lyle et al., 2008; Poewe, Wolters, & Emre, 2006; Ritchie et al., 2004). Another type of drug, *memantine* (Namenda), affects levels of glutamate (Tariot et al., 2004) and is used to treat moderate to severe Alzheimer's dementia (Kavirajan, 2009; Laks & Engelhardt, 2008). Although these drugs can help some patients (Atri et al., 2008; Cummings, Mackell, & Kaufer, 2008; Homma et al., 2008), they are new, and few carefully controlled studies of these medications have been completed. Moreover, it is unknown what the long-term effects of these drugs may be (Langa, Foster, & Larson, 2004; Ringman & Cummings, 2006). These medications may also be given to patients with dementia due to Parkinson's disease.

Antipsychotic medications are sometimes given for psychotic symptoms or behavioral disturbances, but the side effects of both traditional and atypical antipsychotics have led researchers to be cautious in advising their long-term use (Ballard & Howard, 2006; Schneider, Dagerman, & Insel, 2006). Patients with dementia due to Lewy bodies should not be given antipsychotic medication for behavioral disturbances because this type of medication makes their symptoms worse.

When patients have high blood pressure (which increases the risk of co-occurring vascular dementia), they may also receive medications to treat that problem.

Targeting Psychological Factors

The American Association for Geriatric Psychiatry (2006) recommends that the first line of intervention for dementia should help patients maintain as high a quality of life as is possible given the symptoms. Such interventions focus on psychological and social factors.

To target psychological factors, people in the early stages of dementia—and their friends and relatives—may be taught strategies and given devices to compensate for memory loss (such as those used for people with amnesic disorder, described earlier). In addition, structured and predictable daily activities can reduce patients' confusion (Spector et al., 2000). Moreover, patients may be given a GPS tracking device to wear so that they can be found relatively quickly and easily if they get lost (Rabin et al., 2006).

The early stages of progressive dementias are often associated with significant anxiety and depression (Porter et al., 2003; Ross, Arnsberger, & Fox, 1998). One type of treatment that may alleviate these comorbid conditions is *reality orientation therapy* (Woods, 2004). This therapy is designed to decrease a patient's confusion by focusing on the here and now. For example, the clinician may frequently repeat the patient's name ("Good morning, Mr. Rodrigues; how are you on this Monday morning,

People with dementia can wander off and become confused about who they are and where their home is. Some people with dementia wear small GPS tracking devices, like the one in this sneaker, so that if they wander off they can be found relatively quickly and easily.

Monitoring whereabouts

1 Wearer's movements picked up by satellite, relayed to monitoring center and made accessible to care takers by internet or phone

2 Electronic alert automatically issued if wearer enters or breaks a pre-defined area

Mr. Rodrigues?”) and remind the patient of the day and time; calendars and clocks are located where the patient can see them easily. Patients whose cognitive functioning is impaired to the point where they are in residential centers are encouraged to join in activities rather than isolate themselves.

Another method that may decrease the depression and anxiety that can accompany progressive cognitive decline is *reminiscence therapy*, which stimulates the patients’ memories that are least affected by dementia—those of their early lives. When providing this treatment, the therapist focuses on patients’ life histories and asks patients to explore and share their experiences with group members or with the therapist; patients may feel relief at being able to remember some information, and their anxiety decreases and their mood then improves (Woods et al., 1998).

To treat behavioral disturbances such as agitation and aggression that sometimes arise with dementia, caregivers—family members and paid caretakers—may first be asked to identify the antecedents and consequences of the problematic behavior (Ayalon et al., 2006; Livingston et al., 2005; Spira & Edelstein, 2006); then, they are advised on how to modify those aspects of the environment or the interactions, when feasible. For instance, if a patient becomes aggressive only at night after waking up to go to the bathroom, a night-light in his or her room may help reduce any anxiety that arises because the patient is confused upon awakening.

Targeting Social Factors

As cognitive and physical functioning declines, patients with dementia may receive services that target social factors—such as *elder day care*, which is a day treatment program for older adults with cognitive or physical impairments. Such day treatment provides a respite for family members who care for the patient and an opportunity for the patient to interact with other people. As the patient continues to decline, however, he or she may require live-in caretakers or full-time care in a nursing home or other residential facility. In addition, the methods used with amnesic patients to create a less cognitively taxing physical environment (for example, labeling doors) may also be used with patients who have dementia.

Taking care of a family member who has Alzheimer’s disease is often extremely stressful, and this stress increases the caretaker’s risk of developing a psychological or medical disorder. (For example, patients may not recognize a family member, and so believe that the family member is an intruder and try to attack him or her or cower in fear.) In recent years, those involved in treating patients with dementia have also reached out to family members who act as caretakers to provide education, support, and, when needed, treatment to help these people develop less stressful ways of interacting with the patients. Such interventions help family members (and indirectly, the patients themselves) function as well as possible under the circumstances.

Diagnosing Mrs. B.’s Problems

Let’s reconsider the specific nature of Mrs. B.’s problems. The neuropsychologist recounted that Mrs. B. knew who and where she was and understood the test instructions. Results of tests of her ability to remember information both immediately after learning it and after a 30-minute delay were normal for her age, which indicated that she probably did not have Alzheimer’s disease or another disorder that involves significant memory impairment (such as amnesic disorder). Instead, the neuropsychologist suggested that Mrs. B.’s problems reflected a mild dementia combined with depression and chronic pain. The neuropsychologist wrote in her report:

“Feedback to Mrs. B. reinforced her belief that her current memory problems do not suggest [Alzheimer’s disease]. She was asked about activities that she enjoys, and we explored ways of increasing her opportunities for these activities with her attendant (e.g., she has recently visited a senior day-care program and hopes to attend one or two days a week). She was encouraged to give her current living situation a longer try, working

with her daughter and staff to improve the most bothersome aspects of the situation. Written reports were provided to the daughter (who is Mrs. B.'s legal guardian) and other medical professionals involved in her care. Feedback was also provided by telephone to the daughter and the referring psychiatrist to answer questions about results and to further discuss approaches to care. Recommendations included continuing psychotherapy and antidepressant medication, negotiating brief written contracts between Mrs. B. and staff members at the board-and-care home to clarify mutual expectations in problem areas, and considering low-dose antipsychotic medication in the event that aggressive and accusatory behaviors escalated despite behavioral intervention. Neither returning home nor moving into the daughter's home was recommended. . . .

"For Mrs. B., things got worse before they got better. Her "fit" in the board-and-care home continued to deteriorate, and after much discussion, she moved back to a nursing home. For a time, she was taking multiple psychoactive medications and her cognitive function deteriorated at a rapid rate. [She was taken off her medications] and her [cognitive functioning] rebounded. A year later, after an intervening small stroke, her memory function is slightly worse, but her mood is brighter, she communicates well, and she has fewer complaints about staff and other residents than she did in the board-and-care home."

(LaRue & Watson, 1998, p. 11)

Key Concepts and Facts About Dementia

- Dementia is the umbrella term for a set of cognitive disorders that involve deficits in memory *and* aphasia, apraxia, agnosia, or problems with executive functions.
- Dementia can give rise to hallucinations and delusions. Conversely, deficits in memory and other cognitive functions may resemble symptoms of dementia but actually arise from mental retardation, schizophrenia, depression, delirium, or amnesic disorder.
- All types of dementia are caused by neurological factors. The most common type of dementia—that due to Alzheimer's disease—is a progressive disorder characterized by neurofibrillary tangles and amyloid plaques in the brain. Although symptoms may emerge before age 65 (early onset, which is highly heritable), the late-onset form (which also has a genetic basis but is less heritable) is much more common. Patients with Alzheimer's may or may not exhibit behavioral disturbances.
- Vascular dementia is caused by reduced or blocked blood flow to the brain, usually because of narrowed arteries or strokes. Vascular dementia can be caused by a series of ministrokes (gradual onset) or a single large stroke (rapid onset); contributory medical problems such as high blood pressure and high cholesterol are often treated aggressively to decrease the likelihood of further brain damage.
- Other types of dementia are caused by medical conditions:
 - Parkinson's disease is a progressive disorder that affects motor functions.
 - Lewy bodies build up inside certain types of neurons and cause the neurons to die, leading to progressive, irreversible dementia.
- HIV disease can eventually destroy white matter and subcortical brain areas; in some cases, this type of dementia can be arrested and even reversed with antiretroviral medication.
- Huntington's disease is a progressive disease that involves death of neurons in brain areas that are involved in cognition, emotion, and motor control.
- Head trauma is caused by accidents or incurred as part of an athletic sport.
- Substance use or dependence can lead to temporary or persistent dementia.
- Treatments for dementia that target neurological factors include medications that affect the levels of acetylcholine and glutamate. Behavioral disturbances that do not decrease with behavioral treatment may be targeted with antipsychotic medications.
- Psychological and social interventions for people with dementia are designed to improve the patients' quality of life. Methods include the use of memory aids, reality orientation therapy, reminiscence therapy, and restructuring the environment.

Making a Diagnosis

- Reread Case 15.4 about Diana Friel McGowin, and determine whether or not her symptoms meet the criteria for dementia. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

SUMMING UP

Summary of Normal Versus Abnormal Aging and Cognitive Functioning

Most aspects of cognitive functioning remain stable during the normal course of aging. However, fluid intelligence and the related abilities of processing speed, recalling verbal information on demand, maintaining attention and multitasking do decline in older adults. But these declines do not generally impair daily functioning.

Although older adults are less likely than younger adults to have a psychological disorder, the disorders that are most common in older adults are depression and generalized anxiety disorder; symptoms of these disorders and of schizophrenia may superficially resemble symptoms of a cognitive disorder.

Brain injury, most commonly from a stroke, can produce various cognitive deficits that may resemble those related to psychological disorders. Among the deficits that may follow a stroke or a head injury are aphasia, agnosia, and apraxia.

In addition, legally prescribed medications or illegal substances can alter awareness, emotional states, and cognitive functioning. A dose that is standard for a younger person can adversely affect an older adult.

Thinking Like a Clinician

Evan is a first-year college student who lives with his grandmother because her home is near his school. Before he started living with her, he had spent only a few days at a time with her, usually on trips with his mother. Now that he's spending more time with his grandmother, he has noticed that she frequently tells him the same stories from her childhood. When she asks him to do an errand, she sometimes forgets the words of the objects she wants him to bring home or the shop she wants him to visit. And sometimes when he enters a room that she's in, she seems momentarily confused about who he is and why he's there. Evan is concerned that there is something "not right" with his grandmother, and is wondering whether he should suggest that she be evaluated by a doctor. Based on what you've learned about normal versus abnormal changes with

aging, what specific advice would you give to Evan to help him determine whether his grandmother's cognitive problems are likely to be those of normal aging (and so Evan need not urgently suggest that she see her doctor)?

Summary of Delirium

According to DSM-IV-TR, delirium is characterized by a disturbance in consciousness and changes in cognitive functioning, particularly mental processes that rely on attention. These symptoms develop rapidly and fluctuate over the course of a 24-hour period. When delirious, people may not know where they are, who they are, or what day (or year) it is. They may also misinterpret stimuli and experience illusions or have hallucinations. Because they believe that these perceptual alterations are real, patients may behave accordingly and get hurt—or hurt other people—in the process. Delirious people may become either restless and agitated or sluggish and lethargic, or they may rapidly alternate between these two states.

Symptoms of depression, anxiety, dissociation, psychosis, and substance use can appear similar to some symptoms of delirium. Delirium can arise from substance intoxication or withdrawal, as well as from a medical condition such as an infection, head trauma, or following surgery.

Treatment for delirium that targets neurological factors often addresses the underlying physical cause, typically through medication. Antipsychotic medication may be given when treatment for the underlying condition isn't possible or will take time to take effect. Treatments that target psychological and social factors include correcting sensory impairments, helping patients increase their awareness of the here and now, and educating people who interact with the delirious patient about the symptoms of the disorder.

Thinking like a clinician

Drew is on his college's football team and had to have surgery on his knee. For the procedure, he had general anesthesia. His mom was with him right after the surgery, and Drew was delirious and remained so for hours. What can you assume, and what should you not assume, about Drew's consciousness, cognitive functions, and emotions? What might be a likely cause of his delirium?

Summary of Amnestic Disorder

Amnestic disorder is characterized by significant deficits solely in memory—other cognitive functions remain relatively intact. People with amnestic disorder may confabulate to fill in memory gaps, and they may not be able to report their history accurately during a clinical interview. Amnestic disorder can be transient or chronic. Amnestic disorder is caused exclusively by two types of neurological factors: (1) substance use, or (2) a medical condition, such as stroke, head trauma, or the effects of surgery.

Rehabilitation focuses on helping amnestic patients learn to use organizational strategies and memory aids. A patient's environment can be structured in order to minimize the amount of information that needs to be remembered to function in daily life.

Thinking like a clinician

Sixty-five-year-old Lucinda recently retired from her job as corporate vice-president of marketing. Lucinda lives alone but frequently visits her son, his wife, and their young daughter. She's noticed lately that she is losing things and often forgets things—such as where her keys are, lunch dates with friends, and other appointments. She's chalking up these problems to her retirement and the resulting changes in her daily patterns. At what point might losing and forgetting things indicate a cognitive disorder? For Lucinda to be diagnosed with amnestic disorder, what should her symptoms be, what should they not be, and why?

Summary of Dementia

Dementia is the umbrella term for a set of cognitive disorders that involve deficits in memory *and* aphasia, apraxia, agnosia, or problems with executive functions. Dementia can give rise to hallucinations and delusions. Conversely, deficits in memory and other cognitive functions may resemble symptoms of dementia but actually arise from mental retardation, schizophrenia, depression, delirium, or amnestic disorder.

All types of dementia are caused by neurological factors. The most common type of dementia—that due to Alzheimer's disease—is a progressive disorder characterized by neurofibrillary tangles and amyloid plaques in the

brain. Although symptoms may emerge before age 65, the late-onset form is much more common. Patients with Alzheimer's may or may not exhibit behavioral disturbances. Vascular dementia is caused by reduced or blocked blood flow to the brain, usually because of narrowed arteries or strokes. Vascular dementia can be caused by a series of ministrokes (gradual onset) or a single large stroke (rapid onset); contributory medical problems such as high blood pressure and high cholesterol are often treated aggressively to decrease the likelihood of further brain damage. Other types of dementia are caused by medical conditions: Parkinson's disease, Lewy bodies, HIV disease (this type of dementia can be arrested or even reversed with antiretroviral medications), Huntington's disease, head trauma, or substance use or withdrawal.

Treatments for dementia that target neurological factors include medications that affect the levels of acetylcholine and glutamate. Behavioral disturbances that do not decrease with behavioral treatment may be targeted with antipsychotic medications.

Psychological and social interventions for people with dementia are designed to improve the patients' quality of life. Methods include the use of memory aids, reality orientation therapy, reminiscence therapy, and restructuring their environment.

Thinking like a clinician

What symptoms would Lucinda, described above, need to display in order to be diagnosed with dementia? If you knew only that Lucinda had been diagnosed with dementia, what should and shouldn't you assume about its cause(s) and her prognosis?

Key Terms

- Cognitive disorders (p. 681)
- Crystallized intelligence (p. 683)
- Fluid intelligence (p. 683)
- Stroke (p. 687)
- Aphasia (p. 687)
- Broca's aphasia (p. 687)

- Wernicke's aphasia (p. 687)
- Apraxia (p. 688)

Ethical and Legal Issues

It's the early evening rush hour in New York City in January 1998. People are waiting in a subway station for a train to take them home, to meet friends, or to go out to dinner. Kendra Webdale, a 32-year-old woman, is among the people waiting at the platform. Andrew Goldstein, a 29-year-old man, comes up from behind her and pushes her in front of an oncoming train as it enters the station. He murdered her, as many witnesses later testified. This might seem an open-and-shut criminal case, but it's not. Goldstein had a 10-year history of mental illness, had been in and out of psychiatric units and hospitals, and was diagnosed with paranoid schizophrenia.

If Goldstein wasn't in his "right mind" when he pushed Webdale, should he face a trial? And if found guilty, should he go to jail, or perhaps be executed? Or should he be judged and treated as someone who is mentally ill—and if so, why? Are those who commit criminal acts dealt with differently if they are mentally ill? Moreover, what if Goldstein had been seeing a psychotherapist and had mentioned that he might do something like this? Should the therapist have reported his statement to the police? Mental health clinicians are bound by a code of ethics and by state and federal laws. What are the relevant ethical guidelines and laws that affect how mental health clinicians treat their patients? These are the types of questions that address the relationships among the law, ethics, and the reality of mental illness and its treatment.

The laws and ethical codes pertaining to mental illness, treatment, and criminal behavior by the mentally ill evolve over time. As we shall see, even when the law is clear about the type of treatment an individual should receive, financial constraints may prevent the individual from receiving that treatment.

In this chapter, we examine the legal and ethical issues that can affect mental health professionals and their patients, paying particular attention to criminal actions by people who are mentally ill—the circumstances under which they are considered insane, what happens to them when they are dangerous to themselves or others, and whether and when they receive treatment.

Chapter Outline

Ethical Issues

- Maintaining Safety: Confining the Dangerously Mentally Ill Patient

Legal Issues Related to Treatment

- Right to Treatment
- Right to Refuse Treatment
- Competence to Refuse Treatment
- Mental Health and Drug Courts

The Wheels of Justice: Follow-up on Andrew Goldstein

Ethical Issues

Various mental health professionals had some contact with Andrew Goldstein during the years that led up to his pushing Kendra Webdale to her death. Any mental health professional may at times have to balance ethical and legal obligations to a patient against the safety of others. Suppose Goldstein had confided to a mental health professional that he sometimes had impulses to hurt people—impulses that he felt he might not be able to control. How should the clinician treat such information? If Goldstein gave specifics about when, where, or with whom he was likely to become violent, would that affect how the clinician should treat such information? What is the clinician ethically bound to do in such instances? We address these questions in the following sections.

An Ethical Principle: The Role of Confidentiality

Different types of mental health professionals assess, and provide treatment for, psychological problems. Each profession has its own code of ethics, although there are commonalities among all of the codes (Web sites containing the specific codes of ethics for the different types of mental health professionals are listed in Table 16.1). The most important commonality is the ethical requirement to maintain **confidentiality**—not to disclose information about a patient (even whether someone *is* a patient) to others unless legally mandated to do so. Let's look closely at the ethical principle of confidentiality.

The ethical principles and code of conduct of the American Psychological Association requires that mental health records remain confidential. In addition, the clinician must inform patients about the limits of confidentiality—that is, under what circumstances confidentiality may be broken. At first glance, this ethical rule might seem to imply that a clinician would have been required to keep anything Goldstein discussed confidential, even if it concerned violent impulses he felt unable to control. However, the situation is not quite so simple.

Ambiguities Regarding Confidentiality

The principle of confidentiality appears to be straightforward, but some clinical situations are thorny and difficult to resolve. When a therapist is treating a couple, for instance, the therapist is bound by confidentiality, but each person in the couple is not; this means that each partner may tell other people about what transpires in therapy sessions. Similarly, in group therapy, although the therapist is bound by confidentiality, each member is not (although group members are asked not to talk about anything they hear from other members). However, when a patient is a minor (under 18 years of age), the clinician may inform the parents about information that the child has told the clinician. The clinician usually discusses the limits of confidentiality with a child old enough to understand them—or at least discusses possible circumstances in which the clinician may need to share information with parents or others.

David Buffington/age fotostock/Photolibrary

A mental health clinician is bound by confidentiality, but each member of a couple participating in couples therapy is not.

Limits of Confidentiality: HIPAA in Action

Congress passed the Health Insurance Portability and Accountability Act in 2002 (HIPAA; U.S. Department of Health and Human Services, 2002), and in doing so widened the set of circumstances under which confidential information could be shared with other individuals and organizations participating in the care or monitoring of a patient. No longer was the patient's permission to share information with other health providers legally required. HIPAA does recognize the special nature of psychotherapy provided by a mental health clinician, however; patients must provide written consent before clinicians can share notes from their psychotherapy sessions. Without a patient's consent, the clinician can share only limited information—such as the dates of treatment, the patient's diagnosis and prognosis, and the medications prescribed—with other people or organizations involved in the treatment or monitoring of the patient.

Through HIPAA, patients lost an element of control over the distribution of their health records (Appelbaum, 2002). The circumstances under which health care information can be shared without a patient's consent (or even without the patient's being told about it) now include the following (U.S. Department of Health and Human Services, 2002):

1. *During litigation.* The opposing lawyer in a lawsuit can request health information from a provider and must only state that he or she made reasonable attempts to notify the patient about the request for information. During litigation, lawyers can even request the medical records of witnesses!
2. *When the person is a police suspect.* Police officers can request health information about a suspect without having a warrant or being under any judicial oversight.
3. *Marketing efforts by health providers (and their business associates) to patients.* For instance, if a community mental health center were initiating a variety of therapy groups, for people with depression, social phobia, and ADHD, the center would be able to send a brochure about the groups to patients currently receiving treatment at the facility.
4. *Research.* When investigators have approval for a study that uses patients' medical records, the investigators may have access to those records without the patients' explicit permission.

However, unless the sharing of information is specifically to facilitate treatment, the law specifies that the provider should disclose only the minimum necessary information.

Legal Restrictions on Confidentiality

States usually have laws to protect confidentiality. However, most states have exceptions to those rules. Typically, confidentiality can be violated in certain situations:

- when a patient gives the clinician permission to violate confidentiality, for example by explicitly giving permission to a therapist to speak to the patient's spouse;
- when a clinician has reasonable cause to suspect abuse of children, the elderly, or the disabled (in such cases, the clinician usually must report the suspected abuse to the appropriate authorities so that steps can be taken to protect those who cannot otherwise protect themselves);
- when a clinician has reasonable cause to believe that a patient is likely to harm himself or herself significantly or attempt suicide (in this situation, the clinician must take steps to protect the patient); and
- when a clinician has good reason to believe that a patient is likely to inflict significant harm on a specified other person (in this case, the clinician must take steps to protect that other person).

Thus, a clinician should not have violated Goldstein's confidentiality if he spoke in generalities about his violent urges. Even if Goldstein had said that he had

Confidentiality

The ethical requirement not to disclose information about a patient (even whether someone *is* a patient) to others unless legally compelled to do so.

violent impulses that he couldn't control when in subway stations or when around blond-haired women, such a statement would probably not be viewed as posing a specific enough danger to violate confidentiality. The clinician would have been legally compelled to violate Goldstein's confidentiality, however, if he had specifically named Kendra Webdale as someone he planned to harm.

Privileged Communication

Confidentiality is an ethical term. A related *legal* term is **privileged communication**, which refers to confidential information that is protected from being disclosed during legal proceedings. Just as a priest cannot legally be compelled to reveal what was said by a parishioner in the confessional, the Supreme Court has ruled that communication between a patient and a therapist is privileged (*Jaffee v. Redmond*, 1996; Mosher & Swire, 2002). However, not all confidential information is privileged, and vice versa.

The person who shared information with the clinician is usually the one who decides whether it can be revealed, but others can make this decision in certain circumstances. For example, if a judge orders that a defendant must undergo a mental health evaluation, as happened to Goldstein after he was taken into custody, the communication between the mental health clinician(s) doing the evaluation and the defendant may not be considered privileged in some courts, depending on the jurisdiction (Meyer & Weaver, 2006; Myers, 1998). In such a circumstance, in order to comply with the law and behave ethically, the mental health clinician should explain to the defendant at the very beginning of the evaluation that anything said to the clinician may be disclosed to the judge. That is, the defendant should be made aware at the outset about the limits of confidentiality. Whenever the law regarding privileged communication conflicts with the ethics of confidentiality, patients should be told of the limits of confidentiality as soon as possible (Meyer & Weaver, 2006).

Another type of exception to the laws governing privileged communication occurs when a patient (or former patient) initiates a civil lawsuit against another party and raises the issue of personal injury (with mental health consequences) in the suit. An example of this type of case would be one in which a woman sues her employer for anguish that resulted from harassment at work. In these sorts of lawsuits for personal injury, the mental health clinician is legally bound to testify if his or her testimony is relevant to the case (Bartol & Bartol, 2004).

It is not always clear who owns a privileged communication that arises in the context of group therapy. In this situation, the therapist may not be compelled to testify about what transpired, but group members may be. At present, judges decide on a case-by-case basis whether a therapist must testify, depending on the specific circumstances (Meyer & Weaver, 2006).

Informed Consent to Participate in Research on Mental Illness: Can Patients Truly Be Informed?

In Chapter 5, we touched on ethical issues related to research, including the issue of informed consent. But can someone who is mentally ill give truly informed consent to participate in psychological research pertaining to his or her disorder? People who have anxiety disorders may be able to understand fully the research procedure and possible adverse effects, but what about people with schizophrenia? Are such patients' mental processes impaired to the extent that their consent isn't really informed? What about people who are having a first episode of psychosis and agree to participate in a study before the psychotic episode has abated?

The general rule of thumb for researchers is that potential participants must be capable of understanding and reasoning about what they are consenting to (Meyer & Weaver, 2006). Thus, the ability to understand and reason about the research procedure may be more important to informed consent than whether the person is psychotic at the time of consent (Kovnick et al., 2003; Misra & Ganzini, 2004).

Privileged communication

Confidential information that is protected from being disclosed during legal proceedings.

Researchers are developing ways to ensure that patients who may be cognitively impaired by a psychological disorder adequately understand the benefits and risks of their participation in research. For instance, Wirshing and colleagues (2005) developed an educational video to increase awareness about informed consent among patients with schizophrenia. Among other points, the video explained that participants can withdraw from the study at any time. Researchers continue to develop and assess methods to ensure that participants give truly informed consent to participate in research (Eyler, Mirzakhanian, & Jeste, 2005).

Key Concepts and Facts About Ethical Issues

- Each type of mental health professional works under his or her own discipline's ethical code; all disciplines include in their ethical code the principle of confidentiality, which applies to information that patients share with mental health professionals.
- Although the clinician is bound by confidentiality, patients in couples therapy, family therapy, and group therapy are not. When a patient is a minor, the clinician may inform the parents about what the child has said; however, most clinicians discuss the limits of confidentiality with a child old enough to understand.
- Because of HIPAA, the limits of confidentiality have been redefined. Now limited information about a patient may be shared with the patient's other health providers in order to facilitate treatment.
- Although laws protect confidentiality, confidentiality may be violated against a patient's wishes when a clinician has reasonable cause to (1) suspect abuse of children, the elderly, or the disabled or (2) believe that a patient is likely to do significant harm to himself or herself (including attempting suicide) or to a specified other person.
- The legal counterpart of the ethical principle of confidentiality is privileged communication—the protection of confidential information from disclosure during legal proceedings; however, in some circumstances, other people can decide whether the information about a patient should be disclosed.
- Patients who have impaired cognitive processes because of a psychological disorder (such as schizophrenia) may be able to provide informed consent to participate in research if they can understand what they are consenting to and can reason about it.

Criminal Actions and Insanity

After Andrew Goldstein pushed Kendra Webdale in front of the oncoming subway train, other passengers detained him until the police arrived. When taken to the police station, he explained in a signed statement why he pushed her: "I felt a sensation like something was entering me like a ghost or a spirit or something like that. . . . When I have the sensation that something is entering me, I get the urge to push, shove, or sidekick" (Rohde, 1999b).

Goldstein then said he "watched in 'horror'" as the train ran over Webdale, after which he is reported to have turned to the man next to him, "raised his arms in the air and said, 'I don't know'" (Rohde, 1999b). When police came, he told them he was a "psychotic patient" who had suffered a "psychotic attack" (Rohde, 1999b) and asked to be taken to the hospital.

Goldstein was arraigned on the charge of second-degree murder and then, perhaps because he seemed to be mentally ill or because of his long psychiatric history, he was taken to a hospital rather than taken to jail. As we shall see, if someone who allegedly committed a crime was mentally ill during or after the criminal act, jail may not be the appropriate place for that person to be. Moreover, treatment—rather than detention—may be an appropriate goal for such a defendant's immediate future. In this section we review the legal and clinical issues that arise after a crime has been committed by someone who is mentally ill.

As discussed in Chapter 1, the term *insanity* is a legal term and is not used in DSM-IV-TR. The legal concept of insanity addresses the question of whether a person was, at the time he or she committed a crime, *criminally responsible*—which

PORTRAIT OF DANIEL M'NAUGHTEN.

The earliest insanity defense case was that of Daniel M'Naghten, a Scottish man whose delusions about the British Prime Minister led him, in 1841, to commit murder. After M'Naghten was found not guilty by reason of insanity, the House of Lords narrowed the criteria for determining insanity; these criteria came to be known as the M'Naghten test.

Criminally responsible

The determination that a defendant's crime was the product of both an *action* or attempted action (the alleged criminal behavior) and his or her *intention* to perform that action.

M'Naghten test (or rule)

The legal test in which a person is considered insane if, because of a "defect of reason, from disease of the mind," he or she did not know what he or she was doing (at the time of committing the act) and did not know that it was wrong.

involves both action and intention: To be **criminally responsible** means that a defendant's crime was the product of both an *action* or attempted action (the alleged criminal behavior) and his or her *intention* to perform that action (Greene et al., 2007; Meyer & Weaver, 2006).

After a crime has been committed and a person has been arrested, the legal system provides two discrete opportunities to determine whether the defendant is suffering from a mental illness: (1) What was the defendant's mental state at the time he or she (allegedly) committed the act? Might the insanity defense be appropriate? (2) What is the defendant's mental state during the time of assessment, leading up to the trial? Can the person adequately assist in his or her own defense? Is the person competent to stand trial? We next discuss each of these circumstances in turn.

While Committing the Crime: Sane or Insane?

In the United States, the legal definition of insanity corresponds to a "test" that is used to determine whether a person is insane. The particular test has changed over time. In the following sections we review the five tests of insanity that have been used, beginning with the first—the M'Naghten test.

The M'Naghten Test

In England in 1841, a Scottish man named Daniel M'Naghten believed that the British Prime Minister, Sir Robert Peel, was personally responsible for M'Naghten's woes. M'Naghten attempted to shoot Peel, but missed him and killed Peel's secretary. During M'Naghten's trial, witnesses testified that he was insane, and the jury found him *not guilty by reason of insanity* (NGBI). This verdict did not sit well with Queen Victoria, reigning monarch at the time, who had been the intended victim of a number of assassination attempts; she asked that it be reviewed. In response, the judges narrowed the insanity defense by limiting the relevance of the defendant's mental state to the time the alleged crime was committed. In what came to be known as the **M'Naghten test (or rule)**, the question asked at a trial became whether, *at the time of committing the act*, the defendant knew what he or she was doing and, if so, knew that the act was wrong—and if he or she did not know this, it was because of "a defect of reason, from disease of the mind." With this narrower test, the judges reversed the verdict and found M'Naghten guilty.

The Irresistible Impulse Test

The M'Naghten test of insanity was adopted in the United States and continued to be used until 1886, when the definition of insanity was widened. The new definition, specified by the **irresistible impulse test**, focused on whether the defendant knew that the criminal behavior was wrong but nonetheless performed it because of an irresistible impulse.

Since the irresistible impulse test was introduced, changes in the legal definition of insanity have centered around the extent to which the criminal behavior was "uncontrollable"; that is, someone might know that the behavior was wrong but nevertheless be unable to stop it (*Parsons v. Alabama*, 1886).

The Durham Test

In 1954, the Supreme Court ruled on a case, *Durham v. U.S.*, and again broadened the test for the insanity defense. The **Durham test** was designed to determine whether the irresistible impulse was *due to mental defect or disorder* present at the time of the alleged crime. The Durham ruling shifted the insanity defense so that it hinged on evidence that the behavior did not arise entirely from free will. The Durham ruling moved away from consideration about morality (knowing "right from wrong") and into the realm of science (having a mental impairment).

There was major drawback to the Durham ruling, however: It left unclear what constituted a mental defect or disorder. For instance, it is possible that someone who was drunk at the time that a crime was committed might be considered to

have a mental defect. And what about someone with antisocial personality disorder (or psychopathy)—might the disorder make that individual able to use the insanity defense? Moreover, how could the court decide whether the criminal behavior was *caused by* the disorder or defect (Greene et al., 2007; Meyer & Weaver, 2006)? This drawback is so significant that most states use other definitions of insanity; only New Hampshire still uses the Durham test (Wrightsmann & Fulero, 2005).

The American Legal Institute Test

To address some of the thorny issues that arose from the Durham test, the American Legal Institute (ALI) proposed two alternative criteria for insanity:

1. The person lacks a *substantial capacity* to appreciate that the behavior was wrong (versus has *no capacity*); or
2. the person has a diminished ability to make his or her behavior conform to the law, that is, an irresistible impulse.

These elements comprise the **American Legal Institute (ALI) test**, and are sometimes referred to as *knowledge (cognition)* and *impulse (volition)* criteria. The ALI test broadened the test for insanity because it provided these two possible criteria (Greene et al., 2007; Meyer & Weaver, 2006). The ALI test also specified that if an individual's only defect or disorder is criminal behavior, the insanity defense cannot be used. This prevented people with antisocial personality disorder (or psychopathy) and people whose only crime is using illegal substances from using these problems as the basis for an insanity defense. The ALI test, or definition, continues to be used by many states.

Insanity Defense Reform Acts

In federal courts, the insanity test changed again in 1984 as a result of John Hinckley's 1981 assassination attempt of then-President Ronald Reagan and Hinckley's subsequent acquittal as not guilty by reason of insanity. Hinckley was a young man with a history of mental illness; he reported that he shot the president in order to impress actress Jodie Foster, about whom he had obsessive delusions (*erotomantic delusions*, described in Chapter 12). In addition to wounding Reagan, Hinckley also shot the president's press secretary (who suffered brain damage and paralysis), as well as a Secret Service agent and a police officer.

The jury found Hinckley insane on the basis of the impulse (volition) element of the ALI test. This means that the jury decided that Hinckley knew it was wrong to shoot the president, but that he was not able to restrain himself. He was sent to a psychiatric hospital, not prison. The fact that Hinckley would serve no prison time greatly disturbed some lawmakers, who, through the Insanity Defense Reform Acts of 1984 and 1988, proceeded to restrict the test for insanity. The new test for insanity, used only in federal court, is most similar to the M'Naghten test—it asks whether the individual, because of a *severe* mental defect or disorder, has a diminished capacity to understand right from wrong (cognition). In an effort to make it more difficult to enter a plea of NGBI, Congress also put an end to the irresistible impulse element (volition) in federal courts. Defendants with mental retardation, psychotic disorders, or mood disorders may qualify for the insanity defense under these new rules, depending on the circumstances of the crime and the defendant's state of mind at the time, but having a disorder *in and of itself* does not constitute an insanity defense. Table 16.2 provides an overview of the various tests of insanity, and Case 16.1 describes a woman who entered a plea of insanity in a murder case.

Irresistible impulse test

The legal test in which a person is considered insane if he or she knew that his or her criminal behavior was wrong but nonetheless performed it because of an irresistible impulse.

Durham test

The legal test in which a person is considered insane if an irresistible impulse to perform criminal behavior was due to a mental defect or disorder present at the time of the crime.

American Legal Institute test (ALI test)

The legal test in which a person is considered insane if a defendant either lacks a substantial capacity to appreciate that his or her behavior was wrong or has a diminished ability to make his or her behavior conform to the law.

John Hinckley developed an obsessive preoccupation with actress Jodie Foster and repeatedly tried to communicate with her by phone and letter. After his attempts were rebuffed, he developed the delusional belief that assassinating President Ronald Reagan would impress Foster and induce her to pay attention to him. In 1981, he acted on that belief and shot the President and three other people.

Andrea Yates, who was tried for murdering her five children, said she drowned them in order to save them from hell. Her lawyers used the insanity defense.

CASE 16.1 ► FROM THE OUTSIDE: The Insanity Defense

In 2001, Andrea Yates confessed to police that she drowned her five children, ages 6 months to 7 years old, in her bathtub. She reported that she believed Satan was inside her, and she drowned them to try to save them from hell. Yates's lawyers said that she had been psychotic at the time of the murders and that she did not know that her actions were wrong. (According to Texas state law, the key element of the insanity defense is knowing that the actions were wrong at the time of the crime.) Her lawyers pointed to her history of mental illness: two previous suicide attempts and four psychiatric hospitalizations for schizophrenia and postpartum depression.

During her trial, an expert witness for the prosecution, psychiatrist Dr. Park Dietz, agreed with previous witnesses that Yates had been psychotic at the time of the drownings, but testified that she was still able to know right from wrong and therefore not insane under Texas law. To support his position, Dr. Dietz brought up the television series *Law and Order*, which he had been told Yates had watched. Dietz, who also served as a consultant to the producers of that television series, testified that shortly before she drowned her children, an episode of *Law and Order* aired that involved a woman with postpartum depression who drowned her children in a bathtub and was declared insane. Prosecutors used Dietz's testimony about the television show to indicate that Yates knew her actions were wrong (Greene et al., 2007).

It turns out, however, that no such episode had been aired; this error was discovered after the jury convicted Yates of murder but before they began deliberating about her punishment. Rather than declare a mistrial, the judge simply told the jurors about the error. Yates was given a life sentence in prison. The appeals court ruled that a mistrial had occurred, and Yates was retried. She was ultimately found not guilty by reason of insanity and placed in a state mental hospital, where she will remain until she is no longer considered a danger to others or herself (Ewing & McCann, 2006).

Table 16.2 ► Tests for the Insanity Defense Used Over Time

Test	Legal Standard
M'Naghten (1843)	"Didn't know what he or she was doing or didn't know it was wrong"
Irresistible impulse (1886)	"Could not control conduct"
Durham (1954)	"Criminal act was caused by mental illness"
American Legal Institute (ALI; 1962)	"Lacks substantial capacity to appreciate the wrongfulness of the conduct <i>or</i> to control it" [emphasis added]
Present federal law (1984 and 1988)	"Lacks capacity to appreciate the wrongfulness of his or her conduct"

Source: Meyer & Weaver, 2006, p. 123, which was adapted in part from Morris, 1986.

The Insanity Defense: Current Issues

The federal requirements for the insanity defense have been narrowed, but ambiguities about its definition have not yet been addressed by the courts. In particular, the courts have yet to resolve two issues about how this defense can be applied:

- whether the person knew the act was *wrong* (a moral question) versus *illegal* (a legal question); and

- whether the person knew *in the abstract* that the act was wrong versus knew *that the specific behavior* was wrong in a particular circumstance (for instance, someone can know that killing people is wrong but, because of a mental illness, believe that killing a particular person for a specific reason is justified: “He was the devil, tempting me, so I had to kill him”).

Let’s examine how these issues about the insanity defense apply to Andrew Goldstein, who pleaded not guilty by reason of insanity. At the trial, an eyewitness to the murder, Ms. Lorenzino, who was standing nearby on the platform, testified that she:

entered the subway station . . . just behind Mr. Goldstein and immediately noticed that he was acting strangely. “I saw a man walking in front of me walking oddly,” Ms. Lorenzino said. She said Mr. Goldstein would take a few “baby steps” on his “tip toes” and then stumble. Mr. Goldstein then started walking normally, then paced furiously back and forth on the southern end of the platform. He mumbled to himself and eyed Ms. Lorenzino and Ms. Webdale, who was reading a magazine about six feet away from Ms. Lorenzino, each time he passed them. Mr. Goldstein’s pacing was so intense that it prompted one man to cry out: “Yo buddy, can you stop pacing? You’re making us nervous,” Ms. Lorenzino said.

As the wait for a train dragged on, Mr. Goldstein walked up to Ms. Lorenzino and stood beside her, she said. “I felt very uncomfortable that he was standing next to me. . . . I said, ‘What are you looking at?’ Then he backed off as if he was frustrated.” Mr. Goldstein paced for a few more minutes, Ms. Lorenzino said, looked down the track as if checking for a train and then walked down the platform to Ms. Webdale. “Do you have the time?” he asked her. Ms. Webdale glanced at her watch and answered, “a little after five,” Ms. Lorenzino said. Mr. Goldstein then positioned himself against the wall behind Ms. Webdale, who returned to her magazine, Ms. Lorenzino said.

When the train sped into the station, she said, Mr. Goldstein “darted” off the wall and violently pushed Ms. Webdale. Ms. Lorenzino said she was struck by how well-planned the push seemed. It gave Ms. Webdale no time to escape. “It was perfect,” she said, referring to the timing. Ms. Webdale’s body never hit the rails, she said, “she just flew right under the train.”

Police Officer Raymond McLoughlin, who also testified yesterday, said he arrived at the station to find people shouting “He’s right here! He’s right here!” He found Mr. Goldstein, who made no effort to escape, sitting on the platform with his legs crossed, surrounded by 20 enraged people who were berating him, he said.

(Rohde, 1999c)

After the murder, during Goldstein’s confession, the prosecutor tried to understand whether Goldstein understood what he was doing, that is, whether his

mental illness caused him to lack a “substantial capacity” to know or appreciate “the nature and consequence” of the attack or know that it was wrong. On the videotape, [the prosecutor] pointedly asks Mr. Goldstein if he thinks it was wrong to push Ms. Webdale. Mr. Goldstein nods and then appears confused. The prosecutor asks him if he understands. Mr. Goldstein says no, and then [the prosecutor] asks him again if he thinks the attack was wrong. “I wasn’t thinking about anything when I pushed her,” Mr. Goldstein said. “It’s like an attack. You don’t really think. . . . It’s like whoosh, whoosh” he added, referring to what he repeatedly described during the confession as the sensation of a “spirit” or “ghost” entering his body that gave him an overwhelming desire to push, kick or shove. Mr. Goldstein says that he pushed Ms. Webdale only “slightly,” but then seems confused again. He blurts out that “I didn’t push her thinking she would end up on tracks” and that he did not know in what direction he was pushing Ms. Webdale.

Mr. Goldstein then says, “I wouldn’t push anyone onto the tracks.”

“Because you know its wrong?” [the prosecutor] asks.

“Yes,” Mr. Goldstein replies.

(Rohde, 1999a)

The prosecutor continues to try to clarify whether Goldstein understood that what he had done to Webdale was wrong:

“But you knew,” says the interrogator, “that if you pushed her off the platform, she might get . . .”

“Killed, yeah,” Mr. Goldstein says.

“And you also knew that if you did that, it would be the wrong thing to do?”

“Yeah, definitely,” Mr. Goldstein says. “I would never do something like that.”

“Well, you did.”

“I know, but the thing is I would never do it on purpose.”

(Winerip, 1999b)

The questioning continues:

“You certainly agree,” [the prosecutor] says, “that you knew what you were doing and you knew it was wrong.”

“Uh-huh,” Mr. Goldstein says.

“When you pushed her onto the tracks to cause her death,” [the prosecutor] says.

“I see,” Mr. Goldstein says.

“No, tell me, did you?”

“Oh, no. I’m sorry?”

“Were you really listening to what I was saying?” [the prosecutor] asks.

“Oh no.”

“Do you agree or disagree that you knew at the time that you pushed her, that it could cause her death?”

“I wasn’t thinking about anything about pushing,” Mr. Goldstein says. “When it happens, I don’t think, it just goes whoosh, whoosh, push, you know,” he says, adding, “It’s like a random variable.”

(Winerip, 1999b)

Assessing Insanity for the Insanity Defense

Interactions such as the one between Goldstein and the prosecutor may illustrate that the defendant’s mental illness affects his or her testimony while on trial. But how does a jury go about determining whether a defendant was insane at the time a crime was perpetrated? The members of a jury rely on testimony about the defendant’s mental state during the time leading up to the crime. Such testimony may come from friends and family members or from witnesses. In Goldstein’s case, witnesses testified that he was acting strangely before pushing Ms. Webdale in front of the train. Jurors may hear about a defendant’s history of mental illness prior to the crime (as occurred for both Goldstein and Hinckley). Expert witnesses who are mental health clinicians may give testimony or submit reports.

How do mental health clinicians determine whether a defendant was insane at the time of the criminal act? What information do they obtain? They may interview the defendant in jail and administer and interpret psychological tests (see Chapter 3). However, such after-the-fact assessments of the defendant’s mental state should take into account events that occurred after the crime and before the clinician’s evaluation. Specifically, the defendant’s mental state may be affected by his or her experiences in jail, medications he or she may be taking, decision to plead NGBI, reactions to the crime, coaching from the defendant’s lawyer or other inmates, and even responses to various assessment methods (Meyer & Weaver, 2006). For example, imagine that a man killed someone when he ran a red light. After the crime, he becomes guilt-ridden and depressed, even suicidal, requiring medication. Assessing his mental status in jail may not shed much light on his mental status at the time of the crime.

Past psychiatric history doesn’t necessarily indicate a person’s mental state at the time he or she committed a crime, but a history of mental illness can provide a context for evaluating the person at the time when the crime was committed. In Goldstein’s case, symptoms of schizophrenia arose when he was 16 years old, and he was committed to a state psychiatric facility when he was in college. Following this stay, he had a lengthy history of mostly brief hospital stays, each stay lasting only until he was “stabilized” (not actively psychotic), and he was then released to outpatient treatment. However, because of a lack of state funds for mental health care, Goldstein’s outpatient treatment usually consisted of almost no treatment. For most of the time he was ill and while an outpatient, he did not have close supervision or monitoring and did not reliably take his medication (Kleinfeld & Roane, 1999). He would eventually deteriorate to the point where he needed to be hospitalized, was stabilized and released again, and then the cycle would be repeated—a process often referred to as a “revolving door.”

States' Rights: Doing Away With the Insanity Defense

Some states have abolished the insanity defense, replacing it with some other type of defense that recognizes that a defendant did not have “free will” while committing a crime (Meyer & Weaver, 2006). Two alternative options are:

- *Diminished capacity*, whereby a person, due to mental illness or defect, was less able to understand that the criminal behavior was wrong or to formulate a specific intention. With this defense, the person is still considered guilty but receives a lesser sentence, is convicted of a lesser crime, or receives a modified form of punishment. This defense contains variations on the two elements of the ALI test of insanity.
- *Guilty but mentally ill*, whereby a convicted defendant is often sent to a psychiatric facility and, if his or her mental state improves over time, may also serve time in prison; alternatively, the defendant may be sent to a prison immediately, where he or she may or may not receive psychiatric care. Note that with guilty but mentally ill, the person isn't acquitted (that is, found not guilty of a crime), and there is no guarantee that mental health services will be provided (Meyer & Weaver, 2006). In fact, in many states, prisoners who have been found guilty but mentally ill receive no more psychological treatment than do other prisoners (Wrightsmann & Fulero, 2005).

With the Insanity Defense, Do People Really “Get Away With Murder”?

After the Hinckley trial, some people perceived the insanity defense as a way to “get away with murder.” But this perception isn't very accurate. Consider a landmark study of 9,000 felony cases across eight states from 1976 to 1987 (Steadman et al., 1993). Among those cases, only 1% used the insanity defense. Further, only one quarter of that 1% of defendants were acquitted (that is, found not guilty of the crime). And of this 0.25%, only 7%—2 cases—were acquitted by a jury rather than a judge. This indicates that the defense of not guilty by reason of insanity was rare and, even where it was employed, was not very successful. Researchers have also compared the average time spent in jail by defendants who were found guilty (5 years) versus the average time spent in a mental hospital by those who were found NGBI (4.7 years) and concluded that when the insanity defense is used successfully, people do not “get away with murder” (Meyer & Weaver, 2006).

After Committing the Crime: Competent to Stand Trial?

Whereas the insanity defense refers to a defendant's mental state at the time the crime was committed, his or her **competency to stand trial** is based on an evaluation of mental state during the time leading up to the trial. That is, does a mental defect or disorder prevent the defendant from participating in his or her own defense?

Competency to stand trial usually entails being able to

- understand the proceedings that will take place,
- understand the facts in the case and the legal options available,
- consult with his or her “lawyer with a reasonable degree of rational understanding” (*Dusky v. United States*, 1960), and
- assist the lawyer in building the defense.

These aspects of competency can be independent of each other; someone can have one ability impaired, but have the others intact (McArthur Research Network, 2006). Until recently, the courts and lawyers have viewed competency to stand trial as an all-or-nothing condition—a defendant either can or can't. With the all-or-nothing standard, Goldstein was found competent to stand trial.

Competency to stand trial

The mental state during the time leading up to the trial that enables a defendant to participate in his or her own defense.

The same all-or-nothing standard is used to determine whether a defendant is *competent to plead guilty* as well as *competent to waive the right to an attorney* (*Godinez v. Moran*, 1993; Perlin, 2000a). If a person is found not competent to stand trial, he or she would also be considered to be not competent to plead guilty or to waive the right to an attorney. Someone who is found not competent is referred for mental health treatment (*Dusky v. United States*, 1960). Some scholars have proposed an alternative term to address the mental competency of all defendants who are nearing legal proceedings: *adjudicative competence* (MacArthur Research Network on Mental Health and the Law, 2001b). Case 16.2 examines the issue of competency to stand trial and waive counsel.

CASE 16.2 ► FROM THE OUTSIDE: Competent to Stand Trial and Waive Counsel

On December 7, 1993, Colin Ferguson intentionally killed 6 people and injured 19 others on a New York commuter train. After his arrest, Ferguson was diagnosed with paranoid personality disorder. Because he was assessed as rational and not delusional, he was deemed competent to stand trial; he fired his attorney when the attorney stated that he would propose an insanity defense. Ferguson then chose to represent himself but did not use the insanity defense. The legal system allowed a mentally ill man to be his own legal counsel, although he did not defend himself adequately. Those following the trial witnessed an intelligent but clearly mentally ill man state that he would call as a witness an exorcist who would testify that a microchip—supposedly planted by the governor of New York—had been lasered out of Ferguson's head by a remote control device (McQuiston, 1995; Perlin, 2000a). That witness was never called to the stand.

Ferguson was convicted on 6 counts of murder and 19 counts of attempted murder.

The MacArthur Foundation has funded a number of research projects investigating legal issues relevant to the mentally ill. For example, *The MacArthur Adjudicative Competence Study* (Hoge et al., 1992, 1997; MacArthur Research Network on Mental Health and the Law, 2001a) found that criminal defense attorneys viewed 15% of their clients as possibly having impaired competence (among 122 randomly selected felony cases). Those defendants most likely to have diminished competence were much less helpful to their attorneys than were those who were clearly competent: They were less actively involved in making decisions and in establishing the

facts of the case. Nevertheless, the attorneys didn't always request that possibly impaired clients be referred for an official mental health evaluation, although the more serious the crime—and more severe the penalty—the more likely the attorneys were to seek an evaluation.

When defendants are found not competent to stand trial, they sometimes are medicated to reduce the symptoms of their mental illness and make them able to stand trial. Occasionally, defendants do not want to take the medication but are given it against their will, perhaps by injection. However, the Supreme Court ruled that mentally ill patients accused of nonviolent crimes could not be forced to take medication in order to become competent to stand trial (*Sell v. United States*, 2003). If it appears unlikely that a person will become competent to stand trial, he or she may be released—but may be civilly committed to a psychiatric facility if deemed a danger to self or others.

In 2002, while suffering from delusions, Brian David Mitchell kidnapped young Elizabeth Smart (see the discussion of the Smart case in Chapter 12). He was apprehended 9 months later (Smart was found alive and returned to her parents) and continues to have delusions. In 2009, he had yet to be found competent to stand trial. A judge had ruled against forcing Mitchell to take medication in order to be competent to stand trial because the judge did not believe that the treatment would succeed (Carlisle, 2009).

Key Concepts and Facts About Criminal Actions and Insanity

- Various tests have been used to determine whether a defendant is insane. The first was the M’Naghten test in 1843, followed by the irresistible impulse test. After almost 70 years came the Durham test. Many states presently use the American Legal Institute (ALI) test, which requires either impaired knowledge that the behavior was wrong (cognition) or impaired capacity to resist the impulse to act illegally (volition). The Insanity Defense Reform Acts of the 1980s did away with the volition element to determine insanity in federal courts.
- Two issues are still to be clarified by the courts: (1) whether someone who is legally insane must have known that the act was “wrong” versus “illegal” and (2) whether insanity depends on knowing in the abstract that an act is wrong versus knowing that the specific behavior is wrong in the particular circumstance.
- To assess insanity, a jury may rely on testimony about the defendant’s mental state during the time leading up to the crime, the defendant’s history of mental illness prior to the crime, and testimony or reports from expert witnesses about the defendant’s mental state or mental illness.
- Mental health clinicians may assess a defendant’s sanity through interviews with the person, psychological tests and questionnaires, and interviews with family members and friends. However, such measures may be affected by the defendant’s experiences in jail, medications he or she may be taking, the decision to plead not guilty by reason of insanity (NGBI), reactions to the crime, coaching from the defendant’s lawyer or other inmates, and the way the defendant responds to various assessment methods. But none of this information

necessarily indicates the defendant’s mental state at the time of the crime.

- Some states offer alternatives to the insanity defense, including those of diminished capacity and guilty but mentally ill.
- Research indicates that acquittal on the basis of the insanity defense is extremely rare, particularly when the decision is made by a jury rather than a judge.
- Competency to stand trial addresses the defendant’s mental state before the trial and whether the defendant is competent to participate in his or her own defense; someone who is not competent to stand trial would also be deemed not competent to plead guilty and not competent to waive the right to an attorney.

Making a Determination

- Do you think that Andrew Goldstein was insane, according to the legal definition (cognition or volition), at the time of the crime? Specifically, how did you arrive at your decision? If you would like more information to determine whether he was legally insane, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 16.2 about Colin Ferguson, and determine whether or not he should have been deemed competent (to stand trial and to waive counsel). Specifically, how did you arrive at your decision? If you would like more information to determine whether he was legally competent, what information—specifically—would you want, and in what ways would the information influence your decision?

Dangerousness: Legal Consequences

Andrew Goldstein’s attack on Kendra Webdale wasn’t the first time he had engaged in dangerous behavior, and his dangerous behavior wasn’t a secret.

In the two years before Kendra Webdale was instantly killed on the tracks, Andrew Goldstein attacked at least 13 other people. The hospital staff members who kept treating and discharging Goldstein knew that he repeatedly attacked strangers in public places.

He was hospitalized after assaulting a psychiatrist at a Queens clinic. [The clinic note from November 14, 1997, reads]: “Suddenly, without any warning, patient springs up and attacks one of [the] doctors, pushing her into a door and then onto the floor. He was hospitalized after threatening a woman, [again] after attacking two strangers at a Burger King [and yet again] after fighting with an apartment mate.” [A note from March 2, 1998, says]: “Broke down roommate’s door because he could not control the impulse.” And particularly chilling, six months before Kendra Webdale’s death, he was hospitalized for striking another woman he did not know on a New York subway.

(Winerip, 1999a)

Goldstein’s history indicates that he had become dangerous. **Dangerousness**, a legal term, refers to someone’s potential to harm self or others. Determining whether someone is dangerous, in this sense, rests on assessing threats of violence to self

Dangerousness

The legal term that refers to someone’s potential to harm self or others.

Table 16.3 ▶ Major Risk Factors
For a Patient to Act
Violently

Patient's Prior Arrests

- More serious crimes
- Greater frequency of crimes

Patient Experienced Child Abuse

- Experienced more serious abuse
- Experienced greater frequency of abuse

Patient's Father . . .

- Used drugs
- Was absent during patient's childhood

Patient's Demographics

- Younger
- Male
- Unemployed

Patient's Diagnosis

- Antisocial personality disorder

Other Clinical Information About Patient

- Has substance abuse problems
- Has problems controlling anger
- Has violent fantasies
- Has had loss of consciousness
- Has been brought to the attention of mental health professionals involuntarily, through the legal system

or to others, or establishing an inability to care for oneself. Dangerousness can be broken down into four components regarding the potential harm (Brooks, 1974; Perlin, 2000c):

1. severity (how much harm might the person inflict?),
2. imminence (how soon might the potential harm occur?),
3. frequency (how often is the person likely to be dangerous?), and
4. probability (how likely is the person to be dangerous?)

Evaluating Dangerousness

Clinicians are sometimes asked to evaluate how dangerous a patient may be—specifically, the severity, imminence, and likelihood of potential harm (Meyer & Weaver, 2006). Such evaluations are either/or in nature—the individual is either deemed not to be dangerous (or at least not dangerous enough to violate confidentiality) or deemed to be dangerous, in which case, confidentiality is broken in order to protect the individual from self-harm or to protect others (Otto, 2000; Quattrocchi & Schopp, 2005). Prior to each discharge from a hospital or psychiatric unit, Goldstein had to be evaluated for dangerousness; he was then discharged because he was deemed not dangerous, or not dangerous enough.

Researchers set out to determine the risk factors that could best identify which patients discharged from psychiatric facilities would subsequently act violently. A summary of the findings appears in Table 16.3. Here are the most notable findings:

- Almost 20% of the patients studied committed at least one violent act within 5 months of their discharge from the psychiatric hospital.
- Men were only somewhat more likely than women to be violent; when female patients were violent, it was generally family members who were victims.
- A history of violent behavior—assessed through hospital records, arrest records, and self-reports—was a strong risk factor for later violence. Part of the problem in evaluating whether Andrew Goldstein was dangerous was that he received care in different facilities, and each facility only had access to information about his violent behavior that led to his admittance to that facility, or his violent behavior while in that facility.
- Persistent thoughts about harming others and higher scores on an anger scale predicted later violence.
- Childhood experiences of serious and frequent abuse, as well as having a father who was a criminal or who engaged in substance abuse, predicted future violent behavior.
- Certain diagnoses, such as substance abuse and antisocial personality disorder, were relatively good predictors of future violence; schizophrenia predicted a *lower* rate of violence. In general, the presence of delusions or hallucinations was not associated with later violence; however, delusions involving suspicions of others and hallucinations that “commanded” a violent act did predict later violence (Steadman et al., 1998).

Confining individuals deemed to be dangerous involves taking away their liberty—their freedom—and is not done lightly. Loitering or yelling at “voices” should not be considered legally dangerous. Rather, the legal system allows an individual to be incarcerated or hospitalized, or to continue to be incarcerated or hospitalized, in only two types of situations:

1. when the individual has not yet committed a violent crime but is perceived to be at imminent risk to do so, or
2. when the individual has already served a prison term or received mandated treatment in a psychiatric hospital and is about to be released but is perceived to be at imminent risk of behaving violently.

To prevent such people from harming themselves or others, the law provides that they can be confined as long as they (continue to) pose a significant danger.

When clinicians evaluate present and future dangerousness, they base their judgment (in part) on an individual's history of such behavior, but such information provides only limited guidance (Perlin, 2000c; Schopp & Quattrocchi, 1984). In fact, whether someone is an imminent danger to self or others is often not clear. For example, although the possible dangerous acts the person may commit should be "imminent," exactly how this word is defined remains unclear (Meyer & Weaver, 2006).

Actual Dangerousness

Mentally ill individuals who engage in criminal acts receive a lot of media attention, which may lead people to believe that criminal behavior by those with mental illnesses is more common than it really is (Pescosolido et al., 1999). In fact, criminal behavior among the mentally ill population is no more common than it is in the general population (Fazel & Grann, 2006). However, two sets of circumstances related to mental illness do increase dangerousness: (1) when the mental illness involves psychosis, and the person may be a danger to self as well as others (Fazel & Grann, 2006; Steadman et al., 1998; Wallace, Mullen, & Burgess, 2004), and especially (2) when serious mental illness is combined with substance abuse (Maden et al., 2004). The relationship between various major mental illnesses, substance use disorders, and violence is shown in Figure 16.1.

It is worth stressing a cautionary note: Although in this section we have focused on the relation between some forms of mental illness and violence, as occurred with Goldstein, most mentally ill people are *not* violent. Indeed, if they are in jail or prison, it is usually for minor nonviolent offenses related to either trying to survive (e.g., stealing food) or to substance abuse—the mental illness is not a direct cause of the incarceration (Hiday & Wales, 2003).

Adam Sylvester/Photo Researchers, Inc.

Although some people with mental illness may create a public nuisance, like this man yelling at voices that only he can hear, such public displays are not dangerous and should not, in and of themselves, lead to hospitalization (Perlin, 2000c).

Figure 16.1

16.1 ► Lifetime Prevalence of Violent Behavior

Substance use disorders (with or without a comorbid major psychological disorder) are associated with a much higher rate of violent behaviors (such as the use of a weapon in a fight or coming to blows with another person) than is observed in the general population (Swanson, 1994).

Confidentiality and the Dangerous Patient: Duty to Warn and Duty to Protect

In the 1960s, University of California college student Prosenjit Poddar liked fellow student Tatiana Tarasoff. However, his interest in her was greater than was hers in him. He became depressed by her rejection and began treatment with a psychologist. During the course of his treatment, his therapist became concerned that Mr. Poddar might hurt or kill Ms. Tarasoff (Poddar had purchased a gun for that purpose). The therapist informed campus police that Poddar might harm Tarasoff. The police briefly restrained him, but they determined that he was rational and not a threat to Tarasoff. Ms. Tarasoff was out of the country at the time, but neither she nor her parents were alerted to the potential danger. Two months later, Poddar killed Tarasoff.

Her parents sued the psychologist, saying that Tarasoff should have been protected either by warning her or by having Poddar committed to a psychiatric facility. In what has become known as the **Tarasoff rule**, the Supreme Court of California (and later courts in other states) ruled that psychologists have a duty to protect potential victims who are in imminent danger (*Tarasoff v. Regents of the University of California*, 1974, 1976). This rule has been extended to other mental health clinicians. There are a few options for mental health professionals who decide that a patient is about to harm a specific person (Quattrocchi & Schopp, 2005):

- warn the intended victim or someone else who can warn the victim,
- notify law enforcement agencies, and
- take other reasonable steps, depending on the situation, such as having the patient voluntarily or involuntarily committed to a psychiatric facility for an extended evaluation (that is, have the patient confined).

The Tarasoff rule effectively extended a clinician's *duty to warn* of imminent harm to a *duty to protect*. The clinician must violate confidentiality in order to take reasonable care to protect an identifiable—or reasonably foreseeable—victim (*Brady v. Hopper*, 1983; *Cairl v. State*, 1982; Egley, 1991; *Emerich v. Philadelphia Center for Human Development*, 1998; Schopp, 1991; *Thompson v. County of Alameda*, 1980). Note, however, that potential danger to property is not sufficient to compel clinicians to violate confidentiality (Meyer & Weaver, 2006).

Maintaining Safety: Confining the Dangerously Mentally Ill Patient

A dangerously mentally ill person can be confined via criminal commitment or civil commitment, described in the following sections.

Criminal Commitment

Criminal commitment is the involuntary commitment to a mental health facility of a person charged with a crime. This can happen before trial or after trial:

- If the defendant hasn't yet had a trial, the time at the mental health facility is used to
 - evaluate whether he or she is competent to proceed with the legal process (for instance, is the defendant competent to stand trial?) and
 - provide treatment so that the defendant can become competent to participate in the legal proceedings.
- If the defendant has had a trial and was acquitted due to insanity (Meyer & Weaver, 2006).

Based on a 1972 ruling (*Jackson v. Indiana*, 1972), it is illegal to confine someone indefinitely under a criminal commitment. Thus, a defendant found not competent to stand trial cannot remain in a mental health facility for life. But the law is unclear as to exactly how long is long enough. Judges have discretion about how

Tarasoff rule

A ruling by the Supreme Court of California (and later other courts) that psychologists have a duty to protect potential victims who are in imminent danger.

Criminal commitment

long they can commit a defendant to a mental health facility to determine whether treatment may lead to competence to stand trial. Such treatment may last several years. If the defendant does not become competent, he or she may not remain committed for the original reason—to receive treatment in order to become competent. In this case, the process of deciding whether he or she should be released from the mental health facility proceeds just as it does for anyone who hasn't been criminally charged. If the individual is deemed to be dangerous, however, he or she may be civilly committed.

Civil Commitment

When an individual hasn't committed a crime but is deemed to be at significant risk of harming himself or herself, or of harming a specific other person, the judicial system can confine that individual in a mental health facility, which is referred to as a **civil commitment**. This is the more common type of commitment.

There are two types of civil commitment: (1) inpatient commitment to a 24-hour inpatient facility, and (2) outpatient commitment to some type of monitoring and/or treatment program (Meyer & Weaver, 2006). Civil commitment grows out of the idea that the government can act as a caregiver, functioning as a “parent” to people who are not able to care for themselves; this legal concept is called *parens patriae*.

The interplay between dangerousness, duty to warn, and civil commitment is illustrated by what happened to Mr. Smith, described in Case 16.3.

CASE 16.3 ► FROM THE OUTSIDE: Civil Commitment and Duty to Warn

Smith has experienced a life-long pattern of difficulty in interacting with others and in functioning effectively in social and occupational situations. He tends to be emotionally uncomfortable and interpersonally awkward. He is inclined to interpret the words and actions of others idiosyncratically, and he characteristically avoids situations that require interpersonal exchanges. He manages to provide for his basic tangible needs, but he remains emotionally withdrawn and interpersonally isolated. He works as a janitor who cleans office buildings at night after closing. He lives in a rooming house populated primarily by residents who have had mental health difficulties. He has no friends among the residents, but he ordinarily gets along in the house without serious difficulty by limiting interaction with the other residents.

Smith has been convicted of assault on three occasions. In each of the first two incidents, he struck another individual, causing minor injuries involving bruises and abrasions. Following the first assault, he was convicted and placed on probation. Following the second conviction, he served 60 days in the county jail and was released on parole. In the third incident, he struck a coworker with a wrench, causing serious but not permanent or life-threatening injuries. He served 6 months in the county jail for that offense. During legal proceedings following each assault, various participants in the legal system realized that he suffered some psychological disorder, but none believed that his impairment was sufficient to support an insanity defense or civil commitment. These individuals recommended that Smith seek treatment after release.

He refused to seek treatment after the first conviction, but he began attending weekly psychotherapy sessions as a condition of his release on parole following the second conviction, and he returned to therapy following release from jail following the third offense. The treating psychologist has diagnosed Smith as suffering from a personality disorder with schizoid and paranoid features. Although he is no longer on parole, Smith has continued attending the weekly sessions. During these sessions, he expressed his belief that the convictions were unfair because in each case he had struck out to protect himself from others who had begun watching him, picking on him, and looking for an opportunity to harm him.

During the last few sessions, Smith told the psychologist that “now, they’re starting again.” He reported having missed work twice during the previous couple of weeks because a coworker named Brown had made comments that Smith interpreted as either warnings or threats. As they were leaving work early in the morning, Brown stated, “be careful” and “watch your step out there.” Smith reported that he was uncertain whether Brown was threatening him or warning him about others who might harm him.

The psychologist encouraged Smith to consider alternative interpretations of Brown's comments. When Smith seemed unable to consider any alternative interpretation, the psychologist became increasingly concerned that Smith's reality testing was deteriorating and that

continued on next page

Civil commitment

The involuntary commitment to a mental health facility of a person deemed to be at significant risk of harming himself or herself or a specific other person.

his persecutory ideation was increasing. The psychologist considered the possibility that a joint session with Smith and Brown might help reduce the risk of another assault. Specifically, Smith might consider alternate interpretations and become reassured that these remarks were innocent, or Brown might realize that it would be advisable to discontinue making such remarks to Smith. Smith responded to the psychologist's suggestion for a joint meeting by becoming increasingly agitated, and he yelled that he had thought their conversations were secret and that he would never again see the psychologist if their conversations were shared with anyone.

The psychologist considered the following [types of] interventions, some of which are mutually compatible: (a) increase the frequency of therapy sessions; (b) emphasize a cognitive reframing of Smith's interpretations of Brown's comments; (c) encourage Smith to explore alternative means of protecting himself from the perceived danger, such as always leaving work at the same time other people leave or always walking home from work on well-lit streets; (d) refer Smith to the clinic psychiatrist for medication review; (e) encourage Smith to consider voluntary inpatient care, particularly if the apparent deterioration worsens.

The psychologist realized that if such approaches failed to ameliorate Smith's deterioration, or if she believed that the risk of another assault was severe or imminent, delegated preventive action [such as civil commitment] might be warranted. Because Smith's functioning seemed unlikely to meet the jurisdiction's criteria for civil commitment, a warning of some kind would be the available delegated intervention. She would be hesitant to warn, however, because she knew of no empirical evidence that warnings reduce violence, and she believed that Smith would view such action as a betrayal and discontinue therapy. Further isolation might also occur if the warning resulted in his dismissal from his job or in counterproductive responses from Brown. The psychologist's prior clinical interventions, primarily cognitive reframing and support, had been effective in ameliorating her client's inclination toward persecutory interpretations of events and in managing the risk associated with exacerbation of these tendencies. She realized that she had no [step-by-step procedure] that allowed her to measure the absolute severity of the risk or the effectiveness of warnings or of these clinical interventions. She weighed the potential costs and benefits of various interventions as she monitored the risk represented by Smith's current functioning.

(Quattrocchi & Schopp, 2005)

Do you think that Smith was dangerous? Did he make a threat regarding an identifiable—or foreseeable—victim? Could Smith's statements be taken in a way to indicate to the psychologist that Brown was the target? If so, the psychologist might be obligated to take steps to warn the victim or to restrain Smith through a civil commitment (although the extent of this obligation differs among various states). But as you can see from this example, some components related to dangerousness—severity, imminence, probability of potential harm, and past frequency of dangerous behavior—are not always known or knowable. (In fact, the article that presented the case of Mr. Smith did not provide information about what the psychologist decided or about what happened to Smith.) Mental health clinicians must base their judgments as best they can, in part on known risk factors.

Civil commitments can conflict with individual rights, so guidelines have been created to protect patients' rights by establishing the circumstances necessary for an involuntary commitment, the duration of such a commitment—and who decides when it ends—as well as the right to refuse a specific type of treatment or treatment in general (Meyer & Weaver, 2006). It may seem that civil commitments are always forced or coerced, but that is not necessarily so. Some civil commitments are voluntary (that is, the patient agrees to the hospitalization); however, some “voluntary” hospitalizations may occur only after substantial coercion (Meyer & Weaver, 2006).

Most people who are civilly committed belong to a subset of the mentally ill population—those who are overrepresented in the revolving door that leads to jails or hospitals. This revolving door evolved because lawmakers and clinicians wanted a more humane approach to dealing with the dangerous mentally ill, by treating them in the least restrictive setting before their condition deteriorates to the point where they harm themselves or others (Hiday, 2003).

Inpatient Commitment

The MacArthur Coercion Study (MacArthur Research Network on Mental Health and the Law, 2001b) found that half of inpatients who initially reported that they didn't need hospitalization and treatment later shifted their views. Looking back, they realized that they did, in fact, need to be hospitalized. The other half of the study's participants continued to believe that they didn't need hospitalization. Participants also noted that family, friends, and mental health professionals' attempts to persuade them by using inducements (for example, saying that voluntarily going along with a hospitalization would give them more control over the process) did not feel like coercion, whereas attempts to persuade them by the use of force or threats (such as the threat of involuntary commitment) did feel like coercion. Moreover, patients were more likely to feel coerced when they believed that they weren't allowed to tell their side of the story or when they believed that others weren't acting out of concern and with respect for them.

Mandated Outpatient Commitment

Mandated outpatient commitment developed in the 1960s and 1970s, along with increasing deinstitutionalization of patients from mental hospitals; the goal was to develop less restrictive alternatives to inpatient care (Hiday, 2003). Such outpatient commitment may consist of legally mandated treatment that includes some type of psychotherapy, medication, or periodic monitoring of the patient by a mental health clinician. The hope is that mandated outpatient commitment will preempt a cycle observed in many patients who have been committed: (1) getting discharged from inpatient care, (2) stopping their medication, (3) becoming dangerous, and (4) ending up back in the hospital through a criminal or civil commitment or landing in jail.

Researchers have investigated whether mandated outpatient commitment is effective: Are the patient and the public safer than if the patient was allowed to obtain voluntary treatment after discharge from inpatient care? Does mandated treatment result in less frequent hospitalizations or incarcerations for the patient? To address these questions, one study compared involuntarily hospitalized patients who either were offered psychosocial treatment and services upon discharge or who were court-ordered to obtain outpatient treatment for 6 months—and made frequent use of services (between 3 and 10 visits/month) (Hiday, 2003; Swartz et al., 2001). The results indicated that those who received mandated outpatient treatment:

- went back into the hospital less frequently and for shorter periods of time,
- were less violent,
- were less likely to be victims of crime themselves, and
- were more likely to take their medication or obtain other treatment, even when the mandated treatment period ended.

(Note, however, that patients in this study were not randomly assigned, so there may have been confounds.) Other studies have found similar benefits of mandated outpatient commitment (Hough & O'Brien, 2005). When people know that they will end up back in the hospital if they don't participate in treatment, they are more likely to comply with that treatment. That said, it is also clear that mandated outpatient commitment is not effective without adequate funding for increased therapeutic services (Perlin, 2003; Rand Corporation, 2001). Let's examine what happens without adequate funding.

The Reality of Treatment for the Chronically Mentally Ill

Coercion to be hospitalized was not an issue for Andrew Goldstein. In fact, he had the opposite problem: He generally *wanted* to be hospitalized and tried repeatedly to make that happen.

He signed himself in voluntarily for all 13 of his hospitalizations. His problem was what happened after discharge. The social workers assigned to plan his release knew he shouldn't have been living on his own, and so did Goldstein, but everywhere they looked they were turned down. They found waiting lists for long-term care at state

hospitals, waiting lists for supervised housing at state-financed group homes, waiting lists for a state-financed intensive-case manager, who would have visited Goldstein daily at his apartment to make sure he was coping and taking his meds.

More than once he requested long-term hospitalization at Creedmoor, the state hospital nearby. In 1997, he walked into the Creedmoor lobby, asking to be admitted. “I want to be hospitalized,” he said. “I need a placement.” But in a cost-cutting drive, New York [had] been pushing hard to reduce its patient census and to shut state hospitals. Goldstein was instead referred to an emergency room, where he stayed overnight and was released.

Again, in July 1998, Goldstein cooperated with psychiatrists, this time during a month-long stay at Brookdale Hospital, in hopes of getting long-term care at Creedmoor. Brookdale psychiatrists had a well-documented case. In a month’s time, Goldstein committed three violent acts: punching the young woman on the subway; attacking a Brookdale therapist, a psychiatrist, a social worker and a ward aide; striking a Brookdale nurse in the face. This time, Creedmoor officials agreed in principle to take him, but explained that there was a waiting list, that they were under orders to give priority to mental patients from prison and that they did not know when they would have an opening. Days later, Goldstein was discharged from Brookdale.

(Winerip, 1999a)

Those who work with the mentally ill said that Mr. Goldstein seemed poorly served by the system. “We’re really concerned that there are huge gaps in the mental health system,” said Jody Silver, director of advocacy for Community Access, a Manhattan program that provides supported housing for people with psychiatric disabilities. “He had a place to live, but he didn’t have support. It sounds like he needed a program with an intensive support service, where he would be visited daily by a caseworker who would monitor his medication and help him with his life. He was totally alone in the community. This person was grossly underserved.”

(Kleinfield & Roane, 1999)

Not only was Goldstein underserved, but so was the public at large. When appropriate services were available to him, Goldstein made good use of them. He spent a year in a residential setting on the grounds of the state hospital—he did well, was cooperative and friendly, and regularly took his medications. But personnel at state hospitals are under pressure to move patients to less expensive programs, even if the patients aren’t ready. Goldstein was considered too low-functioning to qualify for a program that provided less supervision, but he was discharged from the residential program nonetheless—to a home where he received almost no support. A year before the murder he tried, without success, to return to a supervised group but no spaces were available (Winerip, 1999a).

Unfortunately, Goldstein’s history with the mental health system in New York is not unique (see Case 16.4). People with severe mental illness generally don’t receive the care they need (which is also in society’s interest for them to receive) unless their families are wealthy and willing to pay for needed services—long-term hospitalization, supervised housing, or intensive daytime supervision. Even when a defendant is deemed to be mentally ill and ordered to be transferred to a psychiatric facility, space may not be available in such a facility; the options then are to hold the defendant in jail or to release him or her and provide a less intensive form of mental health treatment (Goodnough, 2006).

As discussed in Chapter 12, deinstitutionalization is a reasonable option for those who can benefit from newer, more effective treatments, and providing treatment in the least restrictive alternative setting is also a good idea. Unfortunately, however, such community-based forms of care are not adequately funded, which forces facilities to prioritize and provide treatment only to the sickest, leaving everyone else to make their own way in the system. Thus, most people with severe mental illness lack adequate supervision, care, or housing. They may be living on their own in tiny rented rooms, on the street, in homeless shelters that are not equipped to handle mentally ill people, or they may be in jail. The law may mandate treatment for severely mentally ill individuals, but that doesn’t mean they receive it.

After the murder of Kendra Webdale, New York State passed *Kendra’s law*, allowing family members, roommates, and mental health clinicians to request

court-mandated outpatient treatment for a mentally ill person who refuses treatment; a judge makes the final decision about mandating treatment. The unfortunate irony is that Goldstein sought further treatment, but the lack of social support and available treatment allowed his illness to interfere with his taking medication. In his case, the real culprit may have been the lack of resources to provide the type of support and services that he and others like him—such as the man described Case 16.4—need.

CASE 16.4 ► FROM THE OUTSIDE: A Failed Mandated Outpatient Treatment

On February 12, 2008, David Tarloff murdered psychologist Kathryn Faughey and injured psychiatrist Kent Shinbach in a delusional plan to steal money to fly to Hawaii with his elderly mother. Tarloff, who had been a patient of Shinbach, was hospitalized over a dozen times since 1991, when he was diagnosed with paranoid schizophrenia. In the year leading up to the murders, Tarloff received psychiatric care three times after violent or threatening behavior; he was stabilized on medication and released, despite his family's request for continued inpatient treatment. After release each time, he stopped taking his medication. His family even made use of Kendra's law, so that Tarloff was supposed to receive mandated outpatient treatment, but he avoided the periodic outpatient visits. He was released from a psychiatric unit 10 days before he murdered Faughey.

(Königsberg & Farmer, 2008).

The problems in obtaining appropriate treatment for people with chronic and severe mental illnesses are described by parents of an individual with schizophrenia:

We are the parents of the throwaway schizophrenics, the disposables, the ones who are the most difficult to treat; who are often, as a result of their disability, unable to ask for or accept help. They refuse it.

Left without treatment they continue to suffer. Relatives must stand by and watch, unable to alleviate the suffering which in the main is ignored by the mental health care system until it is too late. It seems to be the same story the world over. We are the people who are told you can't help those who won't help themselves, and we reply under our breath that it seems to us that you won't help those who can't help themselves.

We are the people who mop up the blood of our sons and daughters when they have killed themselves, released from hospital all too soon, or not considered sick enough to be hospitalised. . . . When we ask psychiatrists why they do not declare our obviously ill relatives incompetent, they reply that [mental health law] ties their hands. When we ask the bureaucrats and the politicians how such a law can be passed, they tell us that the psychiatrists are interpreting the law too narrowly. When we turn to the lawyers they tell us that the rights of the individual are paramount. . . . We are left helpless and hopeless, alone in our struggle to save the lives of our children.

(Deveson, 1991, p. 244)

Sexual Predator Laws

People who are repeat sexual offenders—often referred to as *sexual predators*—are clearly dangerous. How do they fit into the legal concept of dangerousness? Are they to be treated as mentally ill? How do the criminal justice and mental health systems view such individuals?

The answers to these questions have evolved over time. Before the 1930s, a sexual offense was viewed as a criminal offense: The perpetrator was seen as able to control the behavior although he or she didn't do so. In the 1930s, sexual offenses were viewed as related to mental illness (sexual psychopaths), and treatment programs for those who committed such offenses proliferated. Unfortunately, the treatments were not effective. By the 1980s, sexual offenses were again seen as crimes for which prison sentences were appropriate consequences. In the 1990s, after highly publicized cases of sexual mutilation and murder of children, some states passed laws to deal with sexually violent predators, who were seen as having no or poor ability to control their impulses. Rather than emphasizing treatment (which had not been effective), the new laws called for incarcerating these individuals as a preventative measure.

Patrick Andrade/The New York Times/Redux

Eight months after David Tarloff committed murder, the judge hearing the case declared Tarloff unfit to stand trial. Tarloff was sent to a psychiatric facility (Eligon, 2008).

In 1997, the Supreme Court upheld the constitutionality of state laws regarding sexual predators (*Kansas v. Hendricks*, 1997); these laws are based on the concept of *parens patriae*, under which the government, as “parent,” has the power to protect the public from threats, as well as the duty to care for those who cannot take care of themselves (Perlin, 2000c). These laws were intended to prevent sex offenders from committing similar offenses, in some cases by ensuring that offenders do not reenter society while there is a significant risk that they will reoffend. At the end of a prison term, if a sexual predator was deemed likely to reoffend *and* was suffering from a mental abnormality or personality disorder, that person could be committed to a psychiatric hospital indefinitely (Winick, 2003).

However, some people viewed such laws as too restrictive, and in 2002, the Supreme Court ruled that in order to commit a sexual offender indefinitely after a jail or prison sentence has been served, it must be demonstrated that the person has difficulty controlling the behavior (*Kansas v. Crane*, 2002; the Supreme Court did not say how to demonstrate this, other than pointing to the individual’s past history). In prison, treatment is voluntary, whereas with commitment it is mandatory.

Key Concepts and Facts About Dangerousness

- Dangerousness has four components related to the potential harm the person may inflict: severity, imminence, frequency, and probability.
- Risk factors for dangerousness include a patient’s prior arrests and violent acts, experience of child abuse, diagnosis of antisocial personality disorder or substance abuse, and the criminal and substance abuse history of the patient’s father. A combination of serious mental illness and substance abuse leads to the highest risk of violence.
- Mental health clinicians have a legal duty to warn and to protect specified potential victims who are judged to be in imminent danger of being harmed by a patient. The clinician may warn the intended victim, notify law enforcement agencies, and/or take other reasonable steps, such as have the patient confined to a psychiatric facility. Clinicians may violate confidentiality to fulfill these duties.
- Criminal commitment may occur before a defendant’s trial to evaluate his or her competence for upcoming legal proceedings or to obtain treatment for the defendant so that he or she can become competent to take part in legal proceedings. When

criminal commitment occurs after a trial, it is because the defendant was acquitted for the reason of insanity.

- Civil commitments occur before a crime has been committed, in order to prevent harm to the patient or others deemed to be at significant risk of harm. Patients may be committed to inpatient or outpatient facilities. Unfortunately, civil commitments do not guarantee appropriate treatment.
- State sexual predator laws are designed to keep indefinitely committed to a psychiatric hospital those sex offenders who are considered to be likely to re-offend. The Supreme Court has upheld such state laws, provided that the state can show that the person has difficulty controlling the behavior.

Making a Determination

- Reread Case 16.3 about Mr. Smith, and determine whether or not his behavior seems to call for civil commitment and create a duty to warn. Specifically, how did you arrive at your decision? If you would like more information to determine whether he should be civilly committed or whether the therapist has a duty to warn, what information—specifically—would you want, and in what ways would the information influence your decision?

Legal Issues Related to Treatment

In the 1960s and 1970s, the courts decided several landmark cases regarding the rights of the mentally ill. These cases addressed the right to treatment and the right to refuse treatment.

Right to Treatment

In 1966 (*Lake v. Cameron*), the Supreme Court ruled that people who are forced to receive treatment through civil commitment should be given the least restrictive alternative treatment available. That is, they should have the type of treatment that infringes the least on their individual liberties. If an individual doesn’t need the 24-hour monitoring and care of an inpatient unit, that person should be treated

in a less restrictive environment (such as in a residential setting and with outpatient treatment).

One year after this ruling, the Supreme Court ruled that civil commitment must entail more than warehousing or confining people; the Court ruled that appropriate treatment must also be provided, while recognizing that treatment might not necessarily be successful (*Rouse v. Cameron*, 1967). In subsequent cases during the 1970s, courts in various jurisdictions outlined specific minimal criteria for such treatment—including the minimum staffing ratio (number of patients per care provider) and number of hours per week of treatment, as well as the need for each patient to have an individualized treatment plan (*Wyatt v. Stickney*, 1971). The specifics of these requirements differ from jurisdiction to jurisdiction.

The Supreme Court also ruled that civil commitment may not be used simply to confine people against their will indefinitely (except as previously noted with some sexual predators). When patients no longer meet the criteria for commitment (that is, they are no longer dangerous) and can survive independently or with help from willing family members, then they must be discharged (*O'Connor v. Donaldson*, 1975). The reasoning behind this ruling is that the purpose of the confinement is treatment, and so when inpatient treatment is no longer required, the person should be released.

Right to Refuse Treatment

A federal district court in New Jersey set another standard when it ruled that a civilly committed patient has the right to refuse treatment (*Rennie v. Klein*, 1978). Generally, this ruling has been applied to a patient's right to refuse to take medications, most frequently traditional antipsychotics that carry the risk of a serious side effect called *tardive dyskinesia* (see Chapter 12) (Perlin, 2000b). However, the court did not establish the right to refuse treatment in all situations. As long as there has been a fair and adequate hearing of the issues involved for a given patient, his or her refusal can be overridden after weighing certain factors (Meyer & Weaver, 2006):

- the patient is physically threatening to others (which may include patients and staff members),
- the proposed treatment carries only a small risk of irreversible side effects,
- there are no less restrictive treatment alternatives available, and
- the patient's capacity to decide rationally about particular treatments is significantly diminished.

Competence to Refuse Treatment

One of the acceptable circumstances for overriding a committed patient's refusal of a treatment is that he or she does not have the capacity to decide rationally about treatment. How can mental health clinicians and the courts determine whether someone is competent to refuse treatment? (Being competent to refuse treatment is different from being competent to stand trial, although both competencies involve some of the same mental processes and abilities.) One study that investigated the general question of competence to refuse treatment (Appelbaum & Grisso, 1995; Grisso & Appelbaum, 1995) found that about half of patients with schizophrenia performed reasonably well on several tasks assessing decision-making ability. Not surprisingly, those with more severe symptoms of schizophrenia did less well. After 2 weeks of treatment, those whose symptoms had improved also improved in their decision-making abilities related to competence. An even greater proportion of patients hospitalized for depression—about 75%—performed adequately on the tasks that assess decision making. Unlike the patients with more severe symptoms of schizophrenia, those with more severe depression were not necessarily less competent to make decisions. Thus, having a severe mental illness did not routinely make these patients “not competent to refuse treatment.”

Some legal scholars and mental health advocates argue that the right to refuse treatment is at odds with outpatient commitment laws, whereby individuals can be forced to take medication, be committed to an inpatient facility, or put in jail if they don't adhere to their outpatient treatment (Perlin, 2003). In fact, although some individuals who receive outpatient commitment may be competent to refuse treatment, the law may not allow them to refuse.

Mental Health and Drug Courts

Federal, state, and local court dockets are filled with cases awaiting a hearing or trial. In order to hasten the speed with which cases are resolved, municipalities have instituted specialized courts, such as divorce courts, to address particular types of problems. Two such special courts are particularly relevant to the mentally ill: drug courts and mental health courts.

Drug courts were developed in Miami in 1989 for first-time drug abusers—those whose substance abuse was viewed as the underlying motivation for their crime (Miethe, Lu, & Reese, 2000). Soon after arrest, these people were offered an alternative to jail: They could attend a drug treatment program, submit to random and frequent drug testing by urinalysis, and meet with the drug court judge regularly. If they did not show up for a court hearing, a bench warrant would be issued within hours and they could be sent to jail. The overall goal of drug courts is to help defendants reintegrate into society.

Drug court programs do not simply aim to decrease substance abuse; they recognize the complex nature of the factors that contribute to such abuse. Thus, drug courts not only promote intensive treatment for drug abuse and relapse prevention—they also encourage education and employment. In fact, participants typically are asked to earn a GED (high school graduate equivalency diploma) and to hold a steady job. Moreover, participants are required to develop a relationship with a mentor in the community and to meet all their financial obligations, such as child support. Some drug court programs also require community service. Abstinence is assessed through frequent random drug testing, and during their time in such a program, less than 10% of participants use drugs.

Relapse rates are between 4% and 20% for those entering a program and even lower (less than 4%) for those who complete one. Many communities have extended drug court programs to include individuals who were previously jailed for substance abuse–related crimes, with equivalent success (Drug Court Clearinghouse and Technical Assistance Project, 1998).

The success of drug courts led to the development of mental health courts, which began in Florida and now exist in most states, but not necessarily in most

Drug courts recognize that maintaining abstinence can depend on a complex interplay of factors, such as educational opportunities and employment.

John Sundlof/Alamy

districts (Council of State Governments, 2005). Mental health courts seek to treat, rather than incarcerate, mentally ill people who are charged with a misdemeanor. Here are some common types of cases heard in mental health courts and the features of such courts (Goldkamp & Irons-Guynn, 2000):

- The defendant's mental illness seems to contribute to the alleged criminal behavior.
- The defendant's behavior has raised concern for public safety.
- The specialized court is voluntary—the defendant must consent to be part of that court rather than the usual court.
- The mental health court tries *not* to send those who are mentally ill to prison.

Some mental health courts do not accept a defendant who has been violent. Other mental health courts will accept violent defendants but will put the defendants in jail if they do not adhere to the plan for treatment (Redlich et al., 2005). Studies report the same basic finding: When mentally ill people receive treatment, they are subsequently less likely to become violent or to reoffend (McNiel & Binder, 2007; Steadman et al., 1998).

Key Concepts and Facts About Treatment and the Legal System

- The Supreme Court has ruled that people who are civilly committed should be given the least restrictive alternative *treatment* available—not simply confinement—while recognizing that treatment might not necessarily be successful. In addition, civil commitments may not be used solely to confine people against their will indefinitely.
- Patients usually have a right to refuse treatment, such as medication. However, patients who have physically threatened other people may be forced to take medication or receive other treatment, as long as there has been a fair and adequate hearing of the issues involved. In addition, the right to refuse treatment may be overridden in certain circumstances, such as when a patient does not have sufficient capacity to decide rationally about particular treatments.
- Defendants may be sent to drug courts if their drug use was the underlying motivation for the crime; in drug court programs, defendants are offered treatment for their substance abuse or dependence, along with random drug testing and educational and job training opportunities. Drug courts have been successful in decreasing rates of relapse and reoffending.
- Mental health courts can mandate treatment for mentally ill defendants; such programs have been found to decrease violence and repeat offending.

The Wheels of Justice: Follow-up on Andrew Goldstein

The jury that heard Andrew Goldstein's case was deadlocked—some jurors voted to convict and some voted him not guilty by reason of insanity. The deadlocked jury meant that another trial was necessary. This time, with Goldstein's permission, his lawyers took him off his medication several weeks before he was to testify so that jurors could see the extent of his mental illness. However, his mental state at the time of trial could not be used to determine his mental status at the time he committed the crime. This strategy was very controversial, and the judge allowed it, provided that Goldstein be asked daily whether he wanted to receive medication and that he be given medication forcibly if he appeared to become not competent to stand trial (Rohde, 2000). Goldstein hit his social worker within several weeks of stopping his medication, which meant that he resumed taking it and did not take the stand. The jury found Goldstein guilty, although they acknowledged that he was mentally ill. They decided that he knew what he was doing when he threw Kendra Webdale onto the tracks, and that he knew it was wrong.

[The witness] Ms. Lorenzino testified that Mr. Goldstein did not simply push Ms. Webdale, but that he picked her up bodily and threw her in front of the train. In interviews,

jurors said that his apparent deliberateness and preparation, as well as the fact that he caught himself before falling in front of the train, helped convince them that he was not psychotic, that he knew what he was doing was wrong.

(Barnes, 2000a)

After his trial, Goldstein was sent to prison, where he was evaluated to determine whether he needed to be admitted to a psychiatric hospital to become stable. If so, once stable, he would be returned to prison. In such cases, hospitalizations are brief, only long enough to get the defendant well enough to return to prison. In 2006, 8 years after the murder, Goldstein's conviction was overturned because of a technical misstep during the second trial. In a third trial, Goldstein's lawyers entered a plea of guilty, with the understanding that he would serve 23 years in prison, followed by 5 years of psychiatric oversight and supervision after his release.

SUMMING UP

Summary of Ethical Issues

Each type of mental health professional works under his or her own discipline's ethical code; all disciplines include in their ethical code the principle of confidentiality, which applies to information that patients share with mental health professionals. Although the clinician is bound by confidentiality, patients in couples therapy, family therapy, and group therapy are not. When a patient is a minor, the clinician may inform the parents about what the child has said; however, most clinicians discuss the limits of confidentiality with a child who is old enough to understand.

Because of HIPAA, the limits on confidentiality have been redefined. Now limited information about a patient may be shared with the patient's other health providers in order to facilitate treatment. Although laws protect confidentiality, confidentiality may be violated against the patient's wishes when a clinician has reasonable cause to (1) suspect abuse of children, the elderly, or the disabled or (2) believe that a patient is likely to do significant harm to himself or herself (including suicide attempts) or a specified other person.

The legal counterpart to the ethical principle of confidentiality is privileged communication—the protection of confidential information from disclosure during legal proceedings; however, in some circumstances, other people can decide whether the information about a patient should be disclosed.

Patients who have impaired cognitive processes because of a psychological disorder (such as schizophrenia) may be able to provide informed consent to participate in research if they can understand what they are consenting to and can reason about it.

Thinking like a clinician

Rina is taking medication and seeing a therapist for depression. During one therapy session, she remarks, "Sometimes I think my family would be better off if I were dead." Based on what you have read, should Rina's therapist violate confidentiality and take steps to prevent Rina from hurting herself? Why or why not?

What if, instead, Rina had said about her multiply handicapped brother, "Sometimes I think my family would be better off if he were dead"? Would your view of whether Rina's therapist should violate confidentiality change—why or why not? What would Rina need to do or say to provide a *clear* indication that the therapist should violate confidentiality?

Summary of Criminal Actions and Insanity

Various tests have been used to determine whether a defendant is insane. The first was the M'Naghten test in 1843, followed by the irresistible impulse test. After almost 70 years came the Durham test. Many states presently use the American Legal Institute (ALI) test, which requires either impaired knowledge that the behavior was wrong (cognition) or impaired capacity to resist the impulse to act illegally (volition). The Insanity Defense Reform Acts of the 1980s did away with the volition element to determine insanity in federal courts.

Two issues are still to be clarified by the courts: (1) whether someone who is legally insane must have known that the act was "wrong" versus "illegal," and (2) whether insanity depends on knowing in the abstract

that an act is wrong versus knowing that the specific behavior is wrong in the particular circumstance. To assess insanity, a jury may rely on testimony about the defendant's mental state during the time leading up to the crime, the defendant's history of mental illness prior to the crime, testimony or reports from expert witnesses about the defendant's mental state or mental illness.

Mental health clinicians may assess a defendant's sanity through interviews with the person, psychological tests and questionnaires, and interviews with family members and friends. However, such measures may be affected by the defendant's experiences in jail, medications he or she may be taking, the decision to plead not guilty by reason of insanity (NGBI), reactions to the crime, coaching from the defendant's lawyer or other inmates, and the way the defendant responds to various assessment methods. But none of this information necessarily indicates the defendant's mental state at the time of the crime. Some states offer alternatives to the insanity defense, including those of diminished capacity and guilty but mentally ill. Research indicates that acquittal on the basis of the insanity defense is extremely rare, particularly when the decision is made by a jury rather than a judge.

Competency to stand trial addresses the defendant's mental state before the trial and whether the defendant is competent to participate in his or her own defense; someone who is not competent to stand trial would also be deemed not competent to plead guilty and not competent to waive the right to an attorney.

Thinking like a clinician

Jon has been arrested for disturbing the peace and destroying private property; at 2 a.m. last

night, he was yelling and kicking over trash cans on Main Street, and broke several store windows. His rant went on for 25 minutes, until the police arrived. Jon initially resisted arrest and then cooperated. It seemed to the police that Jon was behaving as if he were having a manic episode, and, in fact, he had a history of bipolar disorder. How might mental health clinicians and the legal system go about determining whether Jon was “insane” at the time of the crime? What information would you want to know in order to determine whether he was insane? What if, rather than a history of bipolar disorder, Jon had a history of alcohol abuse and dependence and was drunk the night of the crime. Would that change your opinions? Why or why not?

Summary of Dangerousness

Dangerousness has four components related to the potential harm the person may inflict: severity, imminence, frequency, and probability. Risk factors for dangerousness include a patient’s prior arrests and violent acts, experience of child abuse, diagnosis of antisocial personality disorder or substance abuse, and the criminal and substance abuse history of the patient’s father. A combination of serious mental illness and substance abuse leads to the highest risk of violence.

Mental health clinicians have a legal duty to warn and to protect specified potential victims who are judged to be in imminent danger of being harmed by a patient. The clinician may warn the intended victim, notify law enforcement agencies, and/or take other reasonable steps, such as have the patient confined to a psychiatric facility. Clinicians may violate confidentiality to fulfill these duties.

Criminal commitment may occur before a defendant’s trial to evaluate his or her competence for upcoming legal proceedings or to obtain treatment for the defendant so that he or she can become competent to take part in legal proceedings. When criminal commitment occurs after a trial, it is because the defendant was acquitted for the reason of insanity.

Civil commitments occur before a crime has been committed, in order to prevent harm to the patient or others deemed to be at significant risk of harm. Patients may be committed to inpatient or outpatient facilities.

Unfortunately, civil commitments do not guarantee appropriate treatment.

State sexual predator laws are designed to keep indefinitely committed to a psychiatric hospital those sex offenders who are likely to re-offend. The Supreme Court has upheld such state laws, provided that the state can show that the person has difficulty controlling the behavior.

Thinking like a clinician

Tyrone was diagnosed with schizoaffective disorder when he was 25; his mother, ill with diabetes herself, couldn’t supervise and take care of him to the extent that he needed. Cutbacks in mental health services in his community meant that he couldn’t receive adequate services outside of a hospital (“We don’t have any available beds in residential care,” and “We don’t have any available places in the day treatment center—we’re full”). By age 30, he was living on the streets, in jail for petty crimes such as stealing food from a grocery store, and had been treated for brief periods in a psychiatric facility. Based on what you have read, do you think Tyrone is dangerous—why or why not? Suppose, during psychotic episodes, he darts across busy streets—causing car accidents as drivers quickly brake to avoid hitting him. Would he be dangerous then—why or why not? What would be the advantages and disadvantages to him, and to society, of committing him to inpatient treatment? To outpatient treatment?

Summary of Legal Issues Related to Treatment

The Supreme Court has ruled that people who are civilly committed should be given the least restrictive alternative *treatment* available—not simply confinement—while recognizing that treatment might not necessarily be successful. In addition, civil commitments may not be used solely to confine people against their will indefinitely.

Patients usually have a right to refuse treatment, such as medication. However, patients who have physically threatened other people may be forced to take medication or receive other treatment, as long as there has been a fair and adequate hearing of the issues involved. In addition, the right to refuse treatment may be overridden in certain circumstances, such as when a patient does not

have sufficient capacity to decide rationally about particular treatments.

Defendants may be sent to drug courts if their drug use was the underlying motivation for the crime; in drug court programs, defendants are offered treatment for their substance abuse or dependence, along with random drug testing and educational and job training opportunities. Drug courts have been successful in decreasing rates of relapse and reoffending. Mental health courts can mandate treatment for mentally ill defendants; such programs have been found to decrease violence and repeat offending.

Thinking like a clinician

Ella is in the throes of a psychotic episode and is in the hospital. At times, she feels bugs crawling under her skin, and so she viciously scratches herself until she bleeds. At other times, she thinks she has superpowers and can fly—if there were an open window, she’d jump out of it. Her psychiatrist has prescribed an antipsychotic medication, but she won’t take it: “I don’t like the way it makes me feel.” Based on what you have read, do you think Ella has the right to refuse treatment? Why or why not?

GLOSSARY

• A •

Abnormal psychology The subfield of psychology that studies the causes and progression of psychological disorders; also referred to as *psychopathology*.

Abstinence violation effect The condition that arises when the violation of a self-imposed rule about food restriction leads to feeling out of control with food, which then leads to overeating.

Action potential The wave of chemical activity that moves from the cell body down the axon when a neuron fires.

Active phase The phase of a psychological disorder (such as schizophrenia) in which the individual exhibits symptoms that meet all the criteria for the disorder.

Acute stress disorder The anxiety disorder that arises within a month after a traumatic event and that involves reexperiencing of the event, avoiding stimuli related to the event, and symptoms of anxiety, hyperarousal, and dissociation that last for less than a month.

Affect An emotion that is associated with a particular idea or behavior, similar to an attitude.

Age cohort A group of people born in a particular range of years.

Agonists Medications that mimic the effects of a neurotransmitter or neuromodulator and activate a particular type of receptor.

Agoraphobia The persistent avoidance of situations that might trigger panic symptoms or from which escape would be difficult.

Allegiance effect A pattern in which studies conducted by investigators who prefer a particular theoretical orientation tend to obtain data that supports that particular orientation.

Alogia A negative symptom of schizophrenia marked by speaking less than most other people and responding slowly or minimally to questions.

Alzheimer's disease A medical condition in which the afflicted individual initially has problems with both memory and executive function and which leads to progressive dementia.

Amenorrhea The suppression of menstruation; this condition is diagnosed after three consecutive missed menstrual cycles.

American Legal Institute test (ALI test) The legal test in which a person is considered insane if a defendant either lacks a

substantial capacity to appreciate that his or her behavior was wrong or has a diminished ability to make his or her behavior conform to the law.

Amnesia Memory loss, which is usually temporary but, in rare cases, may be permanent.

Amnesic disorder A cognitive disorder characterized by impaired memory while other mental processes remain relatively intact.

Amyloid plaques Fragments of protein that accumulate on the outside surfaces of neurons, particularly neurons in the hippocampus.

Analogue study Research in which treatment is provided in a way that is analogous to the way it is usually provided, but that is conducted under controlled conditions in a laboratory setting, thereby minimizing confounds.

Anhedonia A difficulty or inability to experience pleasure.

Anorexia nervosa An eating disorder characterized by being at least 15% below expected body weight along with using various methods to prevent weight gain.

Antabuse A medication for treating alcohol abuse and dependence that induces violent nausea and vomiting when it is mixed with alcohol.

Antagonists Medications that bind to a receptor site on a dendrite (or cell body) and prevent the neurotransmitter in the synapse from binding to that receptor or cause less of it to bind.

Antipsychotic medications Medications that reduce certain psychotic symptoms; also called *neuroleptic medications*.

Antisocial personality disorder A personality disorder characterized by a persistent disregard for the rights of others.

Anxiety A sense of agitation or nervousness, which is often focused on an upcoming possible danger.

Anxiety disorder A category of psychological disorders in which the primary symptoms involve extreme anxiety, intense arousal, and/or extreme attempts to avoid stimuli that lead to fear and anxiety.

Anxious apprehension Anxiety that arises in response to a high level of fear of a particular stimulus.

Aphasia A neurological condition characterized by problems in producing or comprehending language.

Applied behavior analysis A technique used to modify maladaptive behaviors by reinforcing new behaviors through shaping.

Apraxia A neurological condition characterized by problems in organizing and carrying out voluntary movements even though the muscles themselves are not impaired.

Asperger's disorder A psychological disorder on the autism spectrum characterized by problems with social interaction and narrowed behaviors—similar to but less severe than autism—but in which language and cognitive development are in the normal range; also referred to as *Asperger's syndrome*.

Asylums Institutions to house and care for people who are afflicted with mental illness.

Attention-deficit/hyperactivity disorder (ADHD) A psychological disorder that typically arises in childhood and is characterized by inattention, hyperactivity, and/or impulsivity.

Attrition The reduction in the number of participants during a research study.

Atypical antipsychotics A relatively new class of antipsychotic medications that affect dopamine and serotonin activity but create fewer movement-related side effects than do traditional antipsychotics; also referred to as *second-generation antipsychotics*.

Autistic disorder A pervasive developmental disorder that arises in childhood and is characterized by delayed or impaired communication and social skills, along with restricted and repetitive behaviors and interests; also referred to as *autism*.

Avoidant personality disorder A personality disorder characterized by extreme social inhibition (i.e., extreme shyness) that usually stems from feeling inadequate and being overly sensitive to negative evaluation.

Avolition A negative symptom of schizophrenia marked by difficulty in initiating or following through with activities.

• B •

Behavior modification The use of operant conditioning principles to change maladaptive behavior.

Behavior therapy The form of treatment that rests on the ideas that (1) maladaptive behaviors, cognitions, and emotions stem from previous learning and (2) new learning can allow patients to develop more adaptive behaviors, cognitions, and emotions.

Behavioral genetics The field that investigates the degree to which the variability of characteristics in a population arises from genetic versus environmental factors.

Behaviorism The approach to psychology that focuses on understanding directly observable behaviors in order to understand mental illness and other psychological phenomena.

Benzodiazepines A class of medications commonly known as tranquilizers.

Bias A tendency that distorts data.

Bibliotherapy The use of self-help materials as part of therapy.

Binge eating Eating much more food at one time than most people would eat in the same context.

Binge-eating disorder A provisional diagnosis of the variant of an eating disorder characterized by frequent episodes of rapid uncontrolled eating of large quantities of food, even when not hungry, without subsequent purging; according to DSM-IV-TR, patients with binge-eating disorder receive a diagnosis of EDNOS.

Biofeedback A technique by which a person is trained to bring normally involuntary or unconscious bodily activity, such as heart rate or muscle tension, under voluntary control.

Biological marker A neurological, bodily, or behavioral characteristic that distinguishes people with a psychological disorder (or a first-degree relative with the disorder) from those without the disorder.

Biomedical treatments Treatments that are designed to reduce target symptoms and/or improve quality of life by changing brain functioning, hormonal activity, or another aspect of bodily functioning.

Biopsychosocial approach The view that a psychological disorder arises from the combined influences of three types of factors—biological, psychological, and social.

Bipolar disorders Mood disorders in which a person's mood is often persistently and abnormally upbeat or shifts inappropriately from upbeat to markedly down.

Body dysmorphic disorder A somatoform disorder characterized by excessive preoccupation with a perceived defect or defects in appearance.

Borderline personality disorder A personality disorder characterized by

volatile emotions, an unstable self-image, and impulsive behavior in relationships.

Brain circuits Sets of connected neurons that work together to accomplish a basic process.

Brain systems Sets of brain circuits that work together to accomplish a complex function.

Brief psychotic disorder The psychotic disorder characterized by the sudden onset of positive or disorganized symptoms that last between a day and a month and are followed by a full recovery.

Broca's aphasia A neurological condition characterized by problems producing speech.

Bulimia nervosa An eating disorder characterized by binge eating along with vomiting or other behaviors to compensate for the large number of calories ingested.

• C •

Case studies (in studies of psychopathology) A research method that focuses in detail on one individual and the factors that underlie that person's psychological disorder or disorders.

Catatonia A condition in which an individual remains in an odd posture or position, with rigid muscles, for hours.

Catatonic schizophrenia The subtype of schizophrenia characterized by stiff or "frozen" postures or poses, bizarre jerky movements, or frozen facial expression.

Cerebral cortex The outer layer of cells on the surface of the brain.

Childhood disintegrative disorder A pervasive developmental disorder characterized by normal development until at least 2 years old, followed by a profound loss of communication skills, normal types of play, and bowel control.

Civil commitment The involuntary commitment to a mental health facility of a person deemed to be at significant risk of harming himself or herself or a specific other person.

Classical conditioning A type of learning that occurs when two stimuli are paired so that a neutral stimulus becomes associated with another stimulus that elicits a reflexive behavior; also referred to as *Pavlovian conditioning*.

Client-centered therapy A humanistic therapy developed by Carl Rogers that is intended to promote personal growth so that a client can reach his or her full potential.

Clinical assessment The process of obtaining relevant information and making

a judgment about mental illness based on the information.

Clinical interview A meeting between clinician and patient during which the clinician asks questions related to the patient's symptoms and functioning.

Clinical psychologist A mental health professional who has a doctoral degree that requires several years of related coursework and several years of treating patients while receiving supervision from experienced clinicians.

Cluster A personality disorders Personality disorders characterized by odd or eccentric behaviors that have elements related to those of schizophrenia.

Cluster B personality disorders Personality disorders characterized by emotional, dramatic, or erratic behaviors that involve problems with emotional regulation.

Cluster C personality disorders Personality disorders characterized by anxious or fearful behaviors.

Cognitive disorders A category of psychological disorders in which the primary symptom is significantly reduced mental abilities, relative to a prior level of functioning.

Cognitive distortions Dysfunctional, maladaptive thoughts that are not accurate reflections of reality and contribute to psychological disorders.

Cognitive rehabilitation A form of psychological treatment that is designed to strengthen cognitive abilities through extensive and focused practice; also called *neurocognitive remediation* or *cognitive mediation*.

Cognitive restructuring The process of reorganizing how a person interprets situations and events, which relies on replacing dysfunctional or irrational automatic thoughts with more rational ones.

Cognitive therapy The form of treatment that rests on the ideas that (1) mental contents influence feelings and behavior; (2) irrational thoughts and incorrect beliefs lead to psychological problems; and, (3) correcting such thoughts and beliefs will therefore lead to better mood and more adaptive behavior.

Cognitive-behavior therapy The form of treatment that combines methods from cognitive and behavior therapies.

Common factors Helpful aspects of therapy that are shared by virtually all types of psychotherapy.

Common liabilities model The model that explains how neurological, psychological,

and social factors make a person vulnerable to a variety of problematic behaviors, including substance abuse and dependence; also called *problem behavior theory*.

Communication disorders A set of psychological disorders characterized by significant problems in understanding language or using language to express oneself.

Community care Programs that allow mental health care providers to visit patients in their homes at any time of the day or night; also known as *assertive community treatment*.

Comorbidity The presence of more than one disorder at the same time in a given patient.

Competency to stand trial The mental state during the time leading up to the trial that enables a defendant to participate in his or her own defense.

Complex inheritance The transmission of traits that are expressed along a continuum by the interaction of sets of genes.

Compulsions Repetitive behaviors or mental acts that a person feels driven to carry out and that usually correspond thematically to an obsession.

Computerized axial tomography (CT) A neuroimaging technique that uses X-rays to build a three-dimensional image (CT or CAT scan) of the brain.

Concordance rate The probability that both twins will have a characteristic or disorder, given that one of them has it.

Conditioned emotional responses Emotions and emotion-related behaviors that are classically conditioned.

Conditioned response (CR) A response that comes to be elicited by the previously neutral stimulus that has become a conditioned stimulus.

Conditioned stimulus (CS) A neutral stimulus that, when paired with an unconditioned stimulus, comes to elicit the reflexive behavior.

Conduct disorder A psychological disorder that typically arises in childhood and is characterized by the violation of the basic rights of others or of societal norms that are appropriate to the individual's age.

Confabulate To create stories in order to fill in gaps in memory.

Confidentiality The ethical requirement not to disclose information about a patient (even whether someone *is* a patient) to others unless legally compelled to do so.

Confounding variables (confounds) Factors that might inadvertently affect the variables of interest in an experiment.

Contingency management A procedure for modifying behavior by changing the conditions that led to, or are produced by, it.

Control group A group of participants in an experiment for which the independent variable is not manipulated, but which is otherwise treated identically to the experimental group.

Conversion disorder A somatoform disorder that involves sensory or motor symptoms that do not correspond to symptoms that arise from known medical conditions.

Correlation The relationship between the measurements made of two variables in which a change in the value of one variable is associated with a change in the value of the other variable.

Correlation coefficient A number that quantifies the strength of the correlation between two variables; the correlation coefficient is most typically symbolized by *r*.

Counseling psychologist A mental health professional who has either a Ph.D. degree from a psychology program that focuses on counseling or an Ed.D. degree from a school of education.

Criminal commitment The involuntary commitment to a mental health facility of a person charged with a crime.

Criminally responsible The determination that a defendant's crime was the product of both an *action* or attempted action (the alleged criminal behavior) and his or her *intention* to perform that action.

Crystallized intelligence A type of intelligence that relies on using knowledge to reason; such knowledge has "crystallized" from previous experience.

Culture The shared norms and values of a society that are explicitly and implicitly conveyed to its members by example and through the use of reward and punishment.

Cybertherapy Internet-based therapy.

Cyclothymic disorder A mood disorder characterized by chronic, fluctuating mood disturbance with numerous periods of hypomanic symptoms and numerous periods of depressive symptoms that do not meet the criteria for an MDE.

• D •

Dangerousness The legal term that refers to someone's potential to harm self or others.

Data Methodical observations, which include numerical measurements of phenomena.

Defense mechanisms Unconscious processes that work to transform psychological conflict so as to prevent unacceptable thoughts and drives from reaching consciousness.

Delirium A cognitive disorder characterized by a disturbance in consciousness and changes in cognitive functioning, particularly in attention.

Delirium tremens (DTs) The symptoms of alcohol withdrawal marked by confusion, convulsions, visual hallucinations, and fever.

Delusional disorder The psychotic disorder characterized by the presence of nonbizarre but demonstrably incorrect beliefs that have persisted for more than 1 month.

Delusions Persistent false beliefs that are held despite evidence that the beliefs are incorrect or exaggerate reality.

Dementia A set of cognitive disorders characterized by deficits in learning new information or recalling information already learned *plus* at least one other type of cognitive impairment.

Dementia due to Lewy bodies A type of progressive dementia caused by a type of protein (referred to as Lewy bodies) that builds up inside some types of neurons and can eventually cause them to die.

Dependent personality disorder A personality disorder characterized by submissive and clingy behaviors, based on fear of separation.

Dependent variable A variable that is measured and that may change its values as a result of manipulating the independent variable.

Depersonalization A dissociative symptom in which the perception or experience of self—either one's body or one's mental processes—is altered to the point of feeling like an observer, as though seeing oneself from the "outside."

Depersonalization disorder A dissociative disorder whose primary symptom is a persistent feeling of being detached from one's mental processes or body, although people who have this disorder may also experience derealization.

Derealization A dissociative symptom in which the external world is perceived or experienced as strange or unreal.

Detoxification Medically supervised withdrawal for those with substance dependence; also referred to as *detox*.

Diagnosis The identification of the nature of a disorder.

Diagnostic bias A systematic error in diagnosis.

Dialectical behavior therapy (DBT) The form of treatment that includes elements of CBT as well as an emphasis on validating the patient's experience, a Zen Buddhist approach, and a dialectics component.

Diathesis–stress model The model that proposes that a psychological disorder is triggered when a person with a predisposition—a diathesis—for the particular disorder experiences an environmental event that causes significant stress.

Disorganized schizophrenia The subtype of schizophrenia characterized by disorganized speech and behavior and inappropriate emotional expression.

Dissociation The separation of mental processes—such as perception, memory, and self-awareness—that are normally integrated.

Dissociative amnesia A dissociative disorder in which the sufferer has significantly impaired memory for important experiences or personal information that cannot be explained by ordinary forgetfulness.

Dissociative disorders A category of psychological disorders in which perception, consciousness, memory, or identity are dissociated to the point where the symptoms are pervasive, cause significant distress, and interfere with daily functioning.

Dissociative fugue A dissociative disorder that involves sudden, unplanned travel and difficulty remembering the past, which can lead patients to be confused about who they are and sometimes to take on a new identity.

Dissociative identity disorder (DID) The dissociative disorder characterized by the presence of two or more distinct *alters* (personality states or identities), each with their own characteristics and history, that take turns controlling the person's behavior.

Dizygotic twins Twins who developed from two fertilized eggs and so have the same overlap in genes (50%) as do siblings not conceived at the same time; also referred to as *fraternal twins*.

Dopamine hypothesis The view that schizophrenia arises from an overproduction of dopamine or an increase in the number or sensitivity of dopamine receptors.

Dopamine reward system The system of neurons, primarily in the nucleus accumbens and ventral tegmental area, that relies on dopamine and gives rise to pleasant feelings.

Dose-response relationship The association between more treatment (a higher dose) and greater improvement (a better response).

Double depression Having both major depressive disorder and dysthymic disorder.

Double-blind design A research design in which neither the participant nor the investigator's assistant knows the group to which specific participants have been assigned or the predicted results of the study.

Dream analysis The psychodynamic technique in which the therapist interprets the content of a patient's dreams.

Drug cues The stimuli associated with drug use that come to elicit conditioned responses through their repeated pairings with use of the drug.

Durham test The legal test in which a person is considered insane if an irresistible impulse to perform criminal behavior was due to a mental defect or disorder present at the time of the alleged crime.

Dyslexia A learning disorder characterized by difficulty with reading accuracy, speed, or comprehension that interferes with academic achievement or activities of daily functioning that involve reading.

Dyspareunia A sexual dysfunction characterized by recurrent or persistent genital pain that is associated with sexual intercourse.

Dysthymic disorder A depressive disorder that involves fewer of the symptoms of a major depressive episode, but the symptoms persist for a longer period of time.

• E •

Eating disorder not otherwise specified (EDNOS) The diagnosis given when an individual's symptoms of disordered eating cause significant distress or impair functioning but do not meet the full criteria for a diagnosis of anorexia nervosa or bulimia nervosa.

Eating disorders A category of psychological disorders characterized by abnormal eating and a preoccupation with body image.

Ego According to Freud, the psychic structure that is charged with mediating between the id's demands for immediate gratification and the superego's high standards of morality, as well as the constraints of external reality.

Electroconvulsive therapy (ECT) A procedure that causes a controlled brain seizure in an effort to reduce or eliminate the symptoms of certain psychological disorders.

Elimination disorders A set of psychological disorders characterized by inappropriate urination or defecation.

Emotion A short-lived experience evoked by a stimulus that produces a mental response, a typical behavior, and a positive or negative subjective feeling.

Encopresis An elimination disorder characterized by a child's persistent defecation in improper locations—neither in a toilet nor in a diaper.

Enuresis An elimination disorder characterized by a child's persistent urination in bed or into his or her clothes.

Epidemiology The type of correlational research that investigates the rate of occurrence, the possible causes and risk factors, and the course of diseases or disorders.

Errorless learning techniques Techniques by which patients are explicitly guided in learning a new skill rather than being allowed to figure it out through trial and error.

Etiology The factors that lead a person to develop a psychological disorder.

Executive functions Mental processes involved in planning, organizing, problem solving, abstract thinking, and exercising good judgment.

Exhibitionism A paraphilic disorder in which sexual fantasies, urges, or behaviors hinge on exposing one's genitals to a stranger, usually as a surprise.

Expansive mood A mood that involves unceasing, indiscriminate enthusiasm for interpersonal or sexual interactions or for projects.

Experimenter expectancy effect The investigator's intentionally or unintentionally treating participants in ways that encourage particular types of responses.

Experiments Research studies in which investigators intentionally manipulate one variable at a time, and measure the

consequences of such manipulation on one or more other variables.

Exposure The behavioral technique that involves repeated contact with a feared or arousing stimulus in a controlled setting.

Exposure with response prevention The behavioral technique in which a patient is carefully prevented from engaging in his or her usual maladaptive response after being exposed to a stimulus that usually elicits the response.

External validity A characteristic of a study, indicating that the results generalize from the sample to the population from which it was drawn and from the conditions used in the study to relevant conditions outside the study.

Extinction The process of eliminating a behavior by not reinforcing it.

• F •

Factitious disorder A psychological disorder marked by the false reporting or inducing of medical or psychological symptoms in order to assume a “sick” role and receive attention.

Family therapy The form of treatment that involves either the family as a whole or some portion of it.

Feeding and eating disorders A set of psychological disorders characterized by problems with feeding or eating.

Female orgasmic disorder A sexual dysfunction characterized by a woman’s persistent problem in progressing from normal sexual excitement to orgasm, such that orgasm is delayed or does not occur, despite a normal amount of appropriate stimulation.

Female sexual arousal disorder A sexual dysfunction marked by a woman’s persistent or recurrent difficulty attaining or maintaining engorged genital blood vessels in response to adequate stimulation; formerly referred to as *frigidity*.

Fetishism A paraphilia in which the individual repeatedly uses nonliving objects to achieve or maintain sexual arousal and such an arousal pattern causes significant distress or impairs functioning.

Fight-or-flight response The automatic neurological and bodily response to a perceived threat; also called the *stress response*.

Flat affect A lack of, or considerably diminished, emotional expression, such as occurs when someone speaks robotically and shows little facial expression.

Flight of ideas Thoughts that race faster than they can be said.

Fluid intelligence A type of intelligence that relies on the ability to create new strategies to solve new problems, without relying solely on information previously learned.

Free association The psychodynamic technique in which patients report aloud their train of thought, uncensored.

Frotteurism A paraphilia characterized by recurrent, intense, sexually arousing fantasies, sexual urges, or behaviors that involve touching or rubbing against a nonconsenting person.

Functional magnetic resonance imaging (fMRI) A neuroimaging technique that uses MRI to obtain images of brain functioning, which reveal the extent to which different brain areas are activated during particular tasks.

• G •

Gateway hypothesis The proposal that use can become abuse when “entry” drugs serve as a gateway to (or the first stage in a progression to) use of “harder” drugs.

Gender identity The subjective sense of being male or female, as these categories are defined by the person’s culture.

Gender identity disorder A psychological disorder characterized by a cross-gender identification that leads the individual to be chronically uncomfortable with his or her biological sex.

Gender role The outward behaviors, attitudes, and traits that a culture deems masculine or feminine.

Generalized anxiety disorder (GAD) The anxiety disorder characterized by uncontrollable worry and anxiety about a number of events or activities that are not solely the focus of another Axis I disorder.

Genes Segments of DNA that control the production of particular proteins and other substances.

Genotype The sum of an organism’s genes.

Group therapy The form of treatment in which several patients with similar needs meet together with one or two therapists.

• H •

Habituation The process by which the emotional response to a stimulus that elicits fear, or anxiety is reduced by exposing the patient to the stimulus repeatedly.

Hallucinations Sensations that are so vivid that the perceived objects or events seem real, although they are not.

Heritability An estimate of how much of the variation in a characteristic within a population (in a specific environment) can be attributed to genetics.

High expressed emotion A family interaction style characterized by hostility, unnecessary criticism, or emotional overinvolvement.

Histrionic personality disorder A personality disorder characterized by attention-seeking behaviors and exaggerated and dramatic displays of emotion.

Hormones Neurotransmitter substances that are released directly into the bloodstream and often function primarily as neuromodulators.

Huntington’s disease A progressive disease that kills neurons and affects cognition, emotion, and motor functions; it leads to dementia and eventually results in death.

Hypersomnia Sleeping more hours each day than normal.

Hypervigilance A heightened search for threats.

Hypoactive sexual desire disorder A sexual dysfunction characterized by a persistent or recurrent lack of sexual fantasies or an absence of desire for sexual activity.

Hypochondriasis A somatoform disorder marked by preoccupation with a fear or belief of having a serious disease, but this preoccupation arises because the individual has misinterpreted his or her bodily sensations or symptoms.

Hypothesis A preliminary idea that is proposed to answer a question about a set of observations.

Hysteria An emotional condition marked by extreme excitability and bodily symptoms for which there is no medical explanation; hysteria is not a DSM-IV-TR disorder.

• I •

Id According to Freud, the seat of sexual and aggressive drives, as well as the desire for immediate gratification of physical and psychological needs.

Identity problem A dissociative symptom in which an individual is not sure who he or she is or may assume a new identity.

Inappropriate affect An expression of emotion that is not appropriate to what a person is saying or not appropriate to the situation.

Inclusion The placement of students with disabilities in a regular classroom, with guidelines for any accommodations that

the regular classroom teacher or special education teacher should make.

Independent variable A variable that a researcher manipulates.

Inpatient treatment Treatment that occurs while a patient is in a psychiatric hospital or in a psychiatric unit of a general hospital.

Internal validity A characteristic of a study, indicating that it measures what it purports to measure because it has controlled for confounds.

Interceptive exposure The behavioral therapy method in which patients intentionally elicit the bodily sensations associated with panic so that they can habituate to those sensations and not respond with fear.

Interpersonal therapy (IPT) The form of treatment that is intended to improve the patient's skills in relationships so that they become more satisfying.

Interpretation The psychodynamic technique in which the therapist infers the unconscious meaning or motivation behind a patient's words and behaviors and shares these inferences with the patient.

In vivo exposure The behavioral therapy method that consists of direct exposure to a feared or avoided situation or stimulus.

Irresistible impulse test The legal test in which a person is considered insane if he or she knew that his or her criminal behavior was wrong but nonetheless performed it because of an irresistible impulse.

• L •

Learned helplessness The state of “giving up” that arises when an animal is in an aversive situation where it seems that no action can be effective.

Learning disorder A psychological disorder characterized by a significant disparity between an individual's academic performance and the expected level of performance based on his or her age, intelligence, and education level.

Lithium The oldest mood stabilizer; it is administered as a salt.

Longitudinal studies (in studies of psychopathology) Research studies that are designed to determine whether a given variable is a risk factor by using data collected from the same participants at various points in time.

• M •

Magnetic resonance imaging (MRI) A neuroimaging technique that creates especially sharp images of the brain by measuring the magnetic properties of atoms in the brain; MRI allows more precise diagnoses when brain abnormalities are subtle.

Magnetic resonance spectroscopy (MRS) A neuroimaging technique that uses magnetic resonance to assess levels of neurotransmitter substances in the brain.

Major depressive disorder (MDD) The mood disorder marked by five or more symptoms of an MDE lasting more than 2 weeks.

Major depressive episode (MDE) A mood episode characterized by severe depression that lasts for at least 2 weeks.

Male erectile disorder A sexual dysfunction characterized by a man's persistent or recurrent inability to attain or maintain an adequate erection until the end of sexual activity; sometimes referred to as *impotence*.

Male orgasmic disorder A sexual dysfunction characterized by a man's delay or absence of orgasm.

Malingering Intentional false reporting of symptoms or exaggeration of existing symptoms, either for material gain or to avoid unwanted events.

Managed care A type of health insurance plan that restricts access to specialized medical care by limiting benefits or reimbursement.

Manic episode A period of at least 1 week characterized by abnormal and persistent euphoria or expansive mood or irritability.

Maudsley approach A family treatment for anorexia nervosa that focuses on supporting parents as they determine how to lead their daughter to eat appropriately.

Mendelian inheritance The transmission of traits by separate elements (genes).

Mental contents The specific material that is stored in the mind and operated on by mental processes.

Mental processes The internal operations that underlie cognitive and emotional functions (such as perception, memory, and guilt feelings) and most human behavior.

Mental retardation Intelligence that is significantly below normal—an IQ approximately equal to or less than 70 (where the mean IQ is set at 100)—and that impairs daily functioning; also referred to as *intellectual disability*.

Meta-analysis A research method that statistically combines the results of a number of studies that address the same question to determine the overall effect.

M'Naghten test (or rule) The legal test in which a person is considered insane if, because of a “defect of reason, from disease of the mind,” he or she did not know what he or she was doing (at the time of committing the act) and that it was wrong.

Monoamine oxidase inhibitors (MAOIs) Antidepressant medications that increase the amount of monoamine neurotransmitter in the synapse.

Monozygotic twins Twins who have basically the same genetic makeup (although it may differ in how often specific genes are repeated) because they began life as a single fertilized egg (zygote), which then divided into two embryos; also referred to as *identical twins*.

Mood A persistent emotion that is not attached to a stimulus; it exists in the background and influences mental processes, mental contents, and behavior.

Mood disorders Psychological disorders characterized by prolonged and marked disturbances in mood that affect how people feel, what they believe and expect, how they think and talk, and how they interact with others.

Mood stabilizer A category of medication that minimizes mood swings.

Moral treatment The treatment of the mentally ill that provided an environment in which people with mental illness were treated with kindness and respect and functioned as part of a community.

Motivational enhancement therapy A form of treatment specifically designed to boost a patient's motivation to decrease or stop substance use by highlighting discrepancies between stated personal goals related to substance use and current behavior; also referred to as *motivational interviewing*.

• N •

Narcissistic personality disorder

A personality disorder is characterized by an inflated sense of importance, an excessive desire to be admired, and a lack of empathy.

Negative punishment The type of punishment that takes place when a behavior is followed by the removal of a pleasant or desired event or circumstance, which decreases the probability of that behavior's recurrence.

Negative reinforcement The type of reinforcement that occurs when an aversive or uncomfortable stimulus is *removed* after a behavior, which makes that behavior more likely to be produced again in the future.

Negative symptoms Symptoms of schizophrenia that are marked by the *absence* or reduction of normal mental processes, mental contents, or behaviors.

Neurofibrillary tangles The mass created by tau proteins that become twisted together and destroy the microtubules, leaving the neuron without a distribution system for nutrients.

Neuromodulators Chemicals that modulate (alter) the way neurotransmitters affect the receiving neuron. Some chemicals that act as neurotransmitters can also act as neuromodulators in certain circumstances, and vice versa.

Neurons Brain cells that process information related to physical, mental, and emotional functioning.

Neuropsychological testing The employment of assessment techniques that use behavioral responses to test items in order to draw inferences about brain functioning.

Neuropsychosocial approach The view that a psychological disorder arises from the combined influences of neurological, psychological, and social factors—which affect and are affected by one another through feedback loops.

Neurosis According to psychoanalytic theory, a pattern of thoughts, feelings, or behavior that expresses an unresolved conflict between the ego and the id or between the ego and the superego.

Neurotransmitters Chemicals that are released at the terminal buttons and cross the synaptic cleft.

• 0 •

Objectification theory The theory that girls learn to consider their bodies as objects and commodities.

Observational learning The process of learning through watching what happens to others; also referred to as *modeling*.

Obsessions Thoughts, impulses, or images that persist or recur, are intrusive—and therefore difficult to ignore—and are inappropriate to the situation.

Obsessive-compulsive disorder (OCD) The anxiety disorder characterized by one

or more obsessions, which may occur together with compulsions.

Obsessive-compulsive personality disorder A personality disorder characterized by preoccupations with perfectionism, orderliness, and self-control as well as low levels of flexibility and efficiency.

Operant conditioning A type of learning in which the likelihood that a behavior will be repeated depends on the consequences associated with the behavior.

Oppositional defiant disorder A psychological disorder that typically arises in childhood or adolescence and is characterized by overt disobedience, hostility, defiance, and negativity toward people in authority.

Outpatient treatment Treatment that does not involve an overnight stay in a hospital.

• P •

Pain disorder A somatoform disorder that occurs when psychological factors significantly affect the onset, severity, or maintenance of significant pain.

Panic An extreme sense (or fear) of imminent doom, together with an extreme stress response.

Panic attack A specific period of intense dread, fear, or a sense of imminent doom, accompanied by physical symptoms of a pounding heart, shortness of breath, shakiness, and sweating.

Panic disorder The anxiety disorder characterized by frequent, unexpected panic attacks, along with fear of further attacks and possible restrictions of behavior in order to prevent such attacks.

Paradoxical intention A systems therapy technique in which the therapist suggests that the problem behavior be allowed to continue or even increase in intensity or frequency.

Paranoid personality disorder A personality disorder characterized by persistent and pervasive mistrust and suspiciousness, accompanied by a bias to interpret other people's motives as hostile.

Paranoid schizophrenia The subtype of schizophrenia characterized by the presence of delusions and auditory hallucinations that are limited to specific topics that have a coherent paranoid or grandiose theme.

Paraphilia A sexual disorder characterized by deviant fantasies, objects, or behaviors that play a role in sexual arousal.

Partial cases The designation given to cases in which patients have symptoms that meet only some of the necessary criteria, but not enough symptoms to meet all the criteria for the diagnosis of a disorder.

Partial hospitalization Treatment is provided at a hospital or other facility, but the patient does not sleep there.

Pedophilia A paraphilia characterized by recurrent sexually arousing fantasies, sexual urges, or behaviors involving a child who has not yet gone through puberty (typically aged 13 or younger).

Personality Enduring traits and characteristics that lead a person to behave in relatively predictable ways across a range of situations.

Personality disorders A category of psychological disorders characterized by a pattern of inflexible and maladaptive thoughts, feelings, and behaviors that arise across a range of situations and lead to distress or dysfunction.

Pervasive developmental disorders A set of developmental disorders that have in common severe deficits in communication and in social interaction skills and may also involve stereotyped behaviors and narrow interests.

Phenotype The sum of an organism's observable traits.

Phobia An exaggerated fear of an object or a situation, together with an extreme avoidance of the object or situation.

Phototherapy Treatment for depression that uses full-spectrum lights; also called *light-box therapy*.

Placebo effect A positive effect of a medically inert substance or procedure.

Polysubstance abuse A behavior pattern of abusing more than one substance.

Population The complete set of possible relevant participants.

Positive punishment The type of punishment that takes place when a behavior is followed by an undesirable consequence, which makes the behavior less likely to recur.

Positive reinforcement The type of reinforcement that occurs when a desired reinforcer is received after a behavior, which makes the behavior more likely to occur again in the future.

Positive symptoms Symptoms of schizophrenia that are marked by the

presence of abnormal or distorted mental processes, mental contents, or behaviors.

Positron emission tomography (PET) A neuroimaging technique that measures blood flow (or energy consumption) in the brain and requires introducing a very small amount of a radioactive substance into the bloodstream.

Posttraumatic stress disorder (PTSD) The anxiety disorder that arises a month or more after a traumatic event and that involves a persistent reexperiencing of the event, avoiding stimuli related to the event, and symptoms of anxiety and hyperarousal that persist for at least a month.

Predictions Hypotheses that should be confirmed if a theory is correct.

Premature ejaculation A sexual dysfunction characterized by orgasm and ejaculation that occur earlier than the man expects, usually before, immediately during, or shortly after penetration.

Premorbid Referring to the period of time prior to a patient's illness.

Prevalence The number of people who have a disorder in a given period of time.

Prevention programs Programs that are designed to prevent or inhibit the development or progression of psychological problems or disorders.

Privileged communication Confidential information that is protected from being disclosed during legal proceedings.

Prodromal phase The phase that precedes the onset of a psychological disorder (such as schizophrenia) when symptoms do not yet meet all the criteria for the disorder.

Prodrome Early symptoms of a disorder.

Prognosis The likely course and outcome of a disorder.

Projective test A tool for personality assessment in which the patient is presented with ambiguous stimuli (such as inkblots or stick figures) and is asked to make sense of and explain them.

Psychiatric nurse A mental health professional who has an M.S.N. degree, plus a C.S. certificate in psychiatric nursing.

Psychiatrist A mental health professional who has an M.D. degree and has completed a residency that focuses on mental disorders.

Psychoactive substance A chemical that alters mental ability, mood, or behavior.

Psychoanalysis The intensive psychotherapy based on Freud's view that psychopathology arises from unconscious conflict.

Psychoanalytic theory The theory that thoughts, feelings, and behaviors are a result of conscious and unconscious forces continually interacting in the mind.

Psychodynamic therapy A form of psychotherapy based on psychoanalysis but that involves less frequent sessions, less emphasis on aggressive and sexual drives, and more attention to present experiences.

Psychoeducation The process of educating patients about research findings and therapy procedures relevant to their situation.

Psychological disorder A pattern of thoughts, feelings, or behaviors that causes significant personal *distress*, significant *impairment* in daily life, and/or significant *risk of harm*, any of which is unusual for the context and culture in which it arises.

Psychomotor agitation An inability to sit still, evidenced by pacing, hand wringing, or rubbing or pulling the skin, clothes or other objects.

Psychomotor retardation A slowing of motor functions indicated by slowed bodily movements and speech and lower volume, variety, or amount of speech.

Psychopathy A set of emotional and interpersonal characteristics marked by a lack of empathy, an unmerited feeling of high self-worth, and a refusal to accept responsibility for one's actions.

Psychopharmacology The use of medication to reduce or eradicate symptoms of psychological disorders; also the study of such treatment.

Psychosexual stages According to Freud, the sequence of five distinct stages of development (oral, anal, phallic, latency, and genital) through which children proceed from infancy to adulthood; each stage has a key task that must be completed successfully for healthy psychological development.

Psychosis An impaired ability to perceive reality to the extent that normal functioning is not possible. The two types of psychotic symptoms are hallucinations and delusions.

Punishment The process by which an event or object that is the consequence of a behavior *decreases* the likelihood that the behavior will occur again.

Purging Attempting to reduce calories that have already been consumed by vomiting or using diuretics, laxatives, or enemas.

• R •

Random assignment Assigning participants to each group in a study using a procedure that relies on chance.

Randomized clinical trial (RCT) A research design that has at least two groups—a treatment group and a control group (usually a placebo control)—to which participants are randomly assigned.

Rapid cycling (of moods) Having four or more episodes that meet the criteria for any type of mood episode within 1 year.

Rational-emotive behavior therapy (REBT) The form of treatment in which a patient's irrational thoughts are transformed into rational ones, which in turn leads to more positive emotions and adaptive behaviors.

Reactivity A behavior change that occurs when one becomes aware of being observed.

Receptors Specialized sites on dendrites and cell bodies that respond only to specific molecules.

Reframe A systems therapy technique in which the therapist offers new ways to conceive of, or frame, the family's or identified patient's problem.

Reinforcement The process by which the consequence of a behavior *increases* the likelihood of the behavior's recurrence.

Reliable Classification systems (or measures) that consistently produce the same results.

Relief craving The desire for the temporary emotional relief that can arise from using a substance.

Replication The process of repeating a study using the same data collection methods under identical or nearly identical conditions to obtain data that should have the same characteristics as those from the original study.

Residential treatment Treatment in which patients stay in a staffed facility where they sleep, eat breakfast and dinner, and perhaps take part in evening groups.

Response bias The tendency to respond in a particular way, regardless of what is being asked by the question.

Restrained eating Restricting intake of specific foods or overall number of calories.

Rett's disorder A pervasive developmental disorder that affects only females and is characterized by normal prenatal development and functioning after birth.

through at least 5 months of age, after which the growth of the child's head slows and she loses the ability to control normal muscle movements, interest in other people, and previously developed skills.

Reuptake The process of moving leftover neurotransmitter molecules in the synapse back into the sending neuron.

Reuptake inhibitors Medications that partially block the process by which a neurotransmitter is reabsorbed into the terminal button, thus increasing the amount of the neurotransmitter in the synaptic cleft.

Reward craving The desire for the gratifying effects of using a substance.

• S •

Sample The small portion of a population that is examined in a study.

Sampling bias The distortion that occurs when the participants in an experiment have not been drawn randomly from the relevant population under investigation.

Schizoaffective disorder The psychotic disorder characterized by the presence of both schizophrenia *and* a depressive, manic, or mixed mood episode.

Schizoid personality disorder A personality disorder characterized by a restricted range of emotions in social interactions and few—if any—close relationships.

Schizophrenia A psychological disorder characterized by psychotic symptoms that significantly affect emotions, behavior, and mental processes and mental contents.

Schizophreniform disorder The psychotic disorder characterized by symptoms that meet all the criteria for schizophrenia *except* that the symptoms have been present for only 1–6 months and daily functioning may or may not have declined over that period of time.

Schizotypal personality disorder A personality disorder characterized by eccentric thoughts, perceptions, and behaviors, in addition to having very few close relationships.

Scientific method The process of gathering and interpreting facts that can lead to the formulation of a new theory or the validation or refutation of an existing theory.

Seasonal affective disorder (SAD) Recurrent depression that follows a seasonal pattern.

Secondary reinforcers Objects and events that do not directly satisfy a biological need but are desirable nonetheless.

Selective serotonin reuptake inhibitors (SSRIs) Medications that slow the reuptake of serotonin from the synapse.

Sensate focus exercises A behavioral technique that is assigned as homework in sex therapy, in which an individual or couple seeks to increase awareness of pleasurable sensations that do not involve genital touching, intercourse, or orgasm.

Separation anxiety disorder A psychological disorder that typically arises in childhood and is characterized by excessive anxiety about separation from home or from someone to whom the individual has become attached.

Sex reassignment surgery The procedure in which an individual's genitals (and breasts, for biological women) are surgically altered to appear like those of the other sex.

Sexual aversion disorder A sexual dysfunction characterized by a persistent or recurrent extreme aversion to and avoidance of most genital sexual contact with a partner.

Sexual dysfunctions Sexual disorders that are characterized by problems in the sexual response cycle.

Sexual masochism A paraphilia in which the individual repeatedly becomes sexually aroused by fantasies, urges, or behaviors related to being hurt—specifically, being humiliated or made to suffer in other ways—and this arousal pattern causes significant distress or impairs functioning.

Sexual response cycle The four stages of sexual response—excitement, plateau, orgasm, and resolution—outlined by Masters and Johnson.

Sexual sadism A paraphilia characterized by recurrent sexually arousing fantasies, urges, and behaviors that inflict physical or psychological suffering on another person.

Shaping The process of reinforcing a small component of behavior at a time and then progressively adding components until the desired complex behavior occurs.

Shared psychotic disorder The psychotic disorder in which an individual develops delusions as a result of his or her close relationship with another person who has delusions as part of a psychotic disorder; also known as *folie à deux*.

Single-participant experiments Experiments with only a single participant.

Social causation The hypothesis that the daily stressors of urban life, especially as experienced by people in a lower socioeconomic level, trigger mental illness in those who are vulnerable.

Social desirability A bias toward answering questions in a way that respondents think makes them “look good” (i.e., that he or she thinks is socially desirable), even if the responses are not true.

Social phobia The anxiety disorder characterized by intense fear of public humiliation or embarrassment, together with the avoidance of social situations likely to cause this fear; also called *social anxiety disorder*.

Social selection The hypothesis that those who are mentally ill “drift” to a lower socioeconomic level because of their impairments; also referred to as *social drift*.

Social support The comfort and assistance that an individual receives through interactions with others.

Social worker A mental health professional who has an M.S.W. degree and may have had training to provide psychotherapy to help individuals and families.

Somatization disorder (SD) A somatoform disorder characterized by multiple physical symptoms that are medically unexplained and impair an individual's ability to function.

Somatoform disorders A category of psychological disorders characterized by complaints about physical well-being that cannot be entirely explained by a medical condition, substance use, or another psychological disorder.

Specific factors The characteristics of a particular treatment or technique that lead it to have unique benefits, above and beyond those conferred by common factors.

Specific phobia The anxiety disorder characterized by excessive or unreasonable anxiety or fear related to a specific situation or object.

Stages of change A series of five stages that characterizes how ready a person is to change problematic behaviors: precontemplation, contemplation, preparation, action, and maintenance.

Statistically significant The condition in which the probability of obtaining the value of a statistical test is greater than what would be expected by chance alone.

Stereotyped behaviors Repetitive behaviors—such as body rocking—that do not serve a function; also referred to as *stereotypies*.

Stimulus control The behavioral technique for changing the frequency of a maladaptive conditioned response by controlling the

frequency or intensity of exposure to the stimulus that elicits the response.

Stimulus generalization The process whereby responses come to be elicited by stimuli that are similar to the conditioned stimulus.

Stroke The interruption of normal blood flow to or within the brain, which results in neuronal death.

Substance abuse A pattern of use of a psychoactive substance that leads to harm or other adverse effects.

Substance dependence The persistent and compulsive use of a psychoactive substance, despite its negative effects on work, relationships, health, or its legal consequences.

Substance intoxication The reversible dysfunctional effects on thoughts, feelings, and behavior that arise from the use of a psychoactive substance.

Substance use disorders Psychological disorders characterized by abuse of or dependence on psychoactive substances.

Subthreshold cases The designation given to cases in which patients have symptoms that fit all the necessary criteria, but at levels lower than required for the diagnosis of a disorder.

Suicidal ideation Thoughts of suicide.

Superego According to Freud, the seat of the conscience, which works to impose morality.

Synapse The place where the tip of the axon of one neuron sends signals to another neuron.

Systematic desensitization The behavioral technique of learning to relax in the presence of a feared stimulus.

Systems therapy The form of treatment that is designed to change the communication or behavior patterns of one or more family members in the context of the family as a whole; also known as *family systems therapy*.

• T •

Tarasoff rule A ruling by the Supreme Court of California (and later other courts) that psychologists have a duty to protect potential victims who are in imminent danger.

Tardive dyskinesia An enduring side effect of traditional antipsychotic medications

that produces involuntary lip smacking and odd facial contortions as well as other movement-related symptoms.

Temperament The various aspects of personality that reflect a person's typical emotional state and emotional reactivity (including the speed and strength of reactions to stimuli).

Teratogens Substances or other stimuli that are harmful to a fetus.

Theory A principle or set of principles that explains a set of data.

Theory of mind A theory about other people's mental states (their beliefs, desires, and feelings) that allows a person to predict how other people will react in a given situation.

Therapeutic alliance The positive relationship between the therapist and the patient.

Tic disorders A set of disorders characterized by persistent tics (motor or vocal) that occur many times a day on most days.

Token economy A treatment program that uses "tokens" or chits as secondary reinforcers to change behavior.

Tolerance The physiological response that arises from repeated use of a substance such that more of it is required to obtain the same effect.

Tourette's disorder A tic disorder characterized by recurrent motoric and vocal tics; also referred to as *Tourette syndrome*.

Transcranial magnetic stimulation (TMS) A procedure that sends sequences of short, strong magnetic pulses into the cerebral cortex via a coil placed on the scalp.

Transference The psychodynamic process by which patients interact with the therapist in the same manner that they did with their parents or other important figures in their lives.

Transvestic fetishism A paraphilia in which a heterosexual man cross-dresses in women's clothes for sexual arousal and experiences distress or impaired functioning because of the cross-dressing; formerly called *transvestism*.

Treatment (for psychological disorders) The use of a procedure or substance to reduce or eliminate psychological problems or symptoms of psychological disorders and/or improve quality of life.

Tricyclic antidepressants (TCAs) Older antidepressants named after the three rings of atoms in their molecular structure.

• U •

Unconditioned response (UCR) A behavior that is reflexively elicited by a stimulus.

Unconditioned stimulus (UCS) A stimulus that reflexively elicits a behavior.

Undifferentiated schizophrenia The subtype of schizophrenia characterized by symptoms that do not completely match those specified for the paranoid, disorganized, or catatonic subtype.

• V •

Vaginismus A sexual dysfunction in females in which recurrent or persistent involuntary spasms of the musculature of the outer third of the vagina interfere with sexual intercourse.

Valid Classification systems (or measures) that actually characterize what they are supposed to characterize.

Validate A systems therapy technique by which the therapist demonstrates an understanding of each family member's feelings and desires.

Vascular dementia A type of dementia caused by reduced or blocked blood supply to the brain, which arises from plaque buildup or blood clots.

Vegetative signs (of depression) Psychomotor symptoms as well as changes in appetite, weight, and sleep.

Voyeurism A paraphilia characterized by sexual fantasies, urges, or behaviors that involve observing someone who is in the process of undressing, is nude, or is engaged in sexual activity, when the person being observed has neither consented to nor is aware of being observed.

• W •

Wernicke's aphasia A neurological condition characterized by problems comprehending language and producing meaningful utterances.

Withdrawal The set of symptoms that arises when a regular user decreases or stops intake of an abused substance.

Word salad Disorganized speech consisting of a random stream of seemingly unconnected words.

Overview of DSM-IV-TR Classification of Disorders

Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence

Mental Retardation [on Axis II of DSM-IV-TR]

- Mild Mental Retardation
- Moderate Mental Retardation
- Severe Mental Retardation
- Profound Mental Retardation

Learning Disorders

- Reading Disorder
- Mathematics Disorder
- Disorder of Written Expression
- Learning Disorder Not Otherwise Specified

Motor Skills Disorder

- Developmental Coordination Disorder

Communication Disorders

- Expressive Language Disorder
- Mixed Receptive-Expressive Language Disorder
- Phonological Disorder
- Stuttering
- Communication Disorder Not Otherwise Specified

Pervasive Developmental Disorders

- Autistic Disorder
- Rett's Disorder
- Childhood Disintegrative Disorder
- Asperger's Disorder
- Pervasive Developmental Disorder Not Otherwise Specified

Attention-Deficit and Disruptive Behavior Disorders

- Attention-Deficit/Hyperactivity Disorder
 - Combined Type
 - Predominantly Inattentive Type
 - Predominantly Hyperactive-Impulsive Type
 - Not Otherwise Specified Type
- Conduct Disorder
- Oppositional Defiant Disorder
- Disruptive Behavior Disorder Not Otherwise Specified

Feeding and Eating Disorders of Infancy or Early Childhood

- Pica
- Rumination Disorder
- Feeding Disorder of Infancy or Early Childhood

Tic Disorders

- Tourette's Disorder
- Chronic Motor or Vocal Tic Disorder
- Transient Tic Disorder
- Tic Disorder Not Otherwise Specified

Elimination Disorders

- Encopresis
- Enuresis

Other Disorders of Infancy, Childhood, or Adolescence

- Separation Anxiety Disorder
- Selective Mutism
- Reactive Attachment Disorder or Infancy or Early Childhood
- Stereotypic Movement Disorder
- Disorder of Infancy, Childhood, or Adolescence Not Otherwise Specified

Delirium, Dementia, and Amnestic and Other Cognitive Disorders

Delirium

- Delirium Due to a General Medical Condition
- Substance-Induced Delirium (due to Intoxication or Withdrawal)
- Delirium Due to Multiple Etiologies
- Delirium Not Otherwise Specified

Dementia

- Dementia of the Alzheimer's Type, with Early Onset
- Dementia of the Alzheimer's Type, with Late Onset
- Vascular Dementia
- Dementia Due to HIV Disease
- Dementia Due to Head Trauma
- Dementia Due to Parkinson's Disease
- Dementia Due to Huntington's Disease
- Dementia Due to Pick's Disease
- Dementia Due to Creutzfeldt-Jakob Disease
- Dementia Due to Other General Medical Condition
- Dementia Due to Multiple Etiologies

Amnestic Disorders

- Amnestic Disorder Due to a General Medical Condition
- Substance-Induced Persisting Amnestic Disorder
- Amnestic Disorder Not Otherwise Specified

Other Cognitive Disorders

- Cognitive Disorder Not Otherwise Specified

Substance-Related Disorders

Alcohol Use Disorders

Amphetamine (or Related Substance) Use Disorders

Caffeine Use Disorders

Cannabis Use Disorders

Cocaine Use Disorders

Hallucinogen Use Disorders

Inhalant Use Disorders

Nicotine Use Disorders

Opioid Use Disorders

Phencyclidine (or Related Substance) Use Disorders

Sedative, Hypnotic, or Anxiolytic Substance Use Disorders

Polysubstance Use Disorder

Schizophrenia and Other Psychotic Disorders

Schizophrenia

- Paranoid Type
- Disorganized Type
- Catatonic Type
- Undifferentiated Type
- Residual Type

Schizophreniform Disorder

Schizoaffective Disorder

Delusional Disorder

Brief Psychotic Disorder

Shared Psychotic Disorder

Psychotic Disorder Due to General Medical Condition

Substance-Induced Psychotic Disorder

Psychotic Disorder Not Otherwise Specified

Mood Disorders

Depressive Disorders

- Major Depressive Disorder
 - Single Episode
 - Recurrent
- Dysthymic Disorder
- Depressive Disorder Not Otherwise Specified

Bipolar Disorders

- Bipolar I Disorder
- Bipolar II Disorder
- Cyclothymic Disorder
- Bipolar Disorder Not Otherwise Specified

Mood Disorder Due to a General Medical Condition

Substance-Induced Mood Disorder

Mood Disorder Not Otherwise Specified

Anxiety Disorders

Panic Disorder without Agoraphobia

Panic Disorder with Agoraphobia

Agoraphobia without History of Panic Disorder

Specific Phobia

Social Phobia

Obsessive-Compulsive Disorder

Posttraumatic Stress Disorder
Acute Stress Disorder
Generalized Anxiety Disorder
Anxiety Disorder Due to a General Medical Condition
Substance-Induced Anxiety Disorder
Anxiety Disorder Not Otherwise Specified

Somatoform Disorders

Somatization Disorder
Undifferentiated Somatoform Disorder
Conversion Disorder
Pain Disorder
Hypochondriasis
Body Dysmorphic Disorder
Somatoform Disorder Not Otherwise Specified

Factitious Disorders

Factitious Disorder with Predominantly Psychological Signs and Symptoms
Factitious Disorder with Predominantly Physical Signs and Symptoms
Factitious Disorder Not Otherwise Specified

Dissociative Disorders

Dissociative Amnesia
Dissociative Fugue
Dissociative Identity Disorder
Depersonalization Disorder
Dissociative Disorder Not Otherwise Specified

Sexual and Gender Identity Disorders

Sexual Dysfunctions
Sexual Desire Disorders
Hypoactive Sexual Desire Disorder
Sexual Aversion Disorder
Sexual Arousal Disorders
Female Sexual Arousal Disorder
Male Erectile Disorder
Orgasmic Disorders
Female Orgasmic Disorder
Male Orgasmic Disorder
Premature Ejaculation
Sexual Pain Disorders
Dyspareunia

Vaginismus
Sexual Dysfunction Due to a General Medical Condition
Substance-Induced Sexual Dysfunction
Sexual Dysfunction Not Otherwise Specified

Paraphilias
Exhibitionism
Fetishism
Frotteurism
Pedophilia
Sexual Masochism
Sexual Sadism
Transvestic Fetishism
Voyeurism
Paraphilia Not Otherwise Specified
Gender Identity Disorder
Gender Identity Disorder in Children
Gender Identity Disorder in Adolescents and Adults

Eating Disorders

Anorexia Nervosa
Bulimia Nervosa
Eating Disorder Not Otherwise Specified

Sleep Disorders

Primary Sleep Disorders: Dyssomnias
Primary Insomnia
Primary Hypersomnia
Narcolepsy
Breathing-Related Sleep Disorder
Circadian Rhythm Sleep Disorder
Dyssomnia Not Otherwise Specified
Primary Sleep Disorders: Parasomnias
Nightmare Disorder
Sleep Terror Disorder
Sleepwalking Disorder
Parasomnia Not Otherwise Specified
Sleep Disorder Related to Another Mental Disorder
Sleep Disorder Due to a General Medical Condition
Substance-Induced Sleep Disorder

Impulse-Control Disorders Not Elsewhere Classified

Intermittent Explosive Disorder
Kleptomania
Pyromania
Pathological Gambling

Trichotillomania
Impulse-Control Disorder Not Otherwise Specified

Adjustment Disorders

Adjustment Disorder
With Anxiety
With Depressed Mood
With Disturbance of Conduct
With Mixed Disturbance of Emotions and Conduct
With Mixed Anxiety and Depressed Mood
Unspecified

Personality Disorders [on Axis II of DSM-IV-TR]

Paranoid Personality Disorder
Schizoid Personality Disorder
Schizotypal Personality Disorder
Antisocial Personality Disorder
Borderline Personality Disorder
Histrionic Personality Disorder
Narcissistic Personality Disorder
Avoidant Personality Disorder
Dependent Personality Disorder
Obsessive-Compulsive Personality Disorder
Personality Disorder Not Otherwise Specified

The Five Axes of DSM-IV-TR

- Axis I Clinical Disorders
- Axis II Personality Disorders and Mental Retardation
- Axis III General Medical Conditions
- Axis IV Psychosocial and Environmental Problems
- Axis V Global Assessment of Functioning
